believed that an aggressive glycemic control may induce beneficial “metabolic memory” – be it transiently – as reported in the UKPDS study, and reduce the incidence of microvascular complications [29]. Therefore, patients with T2DM recurrence after metabolic surgery may still continue to experience reduced microvascular and macrovascular complications in the long-term when compared to those who never had their disease controlled.

ABSTRACT

Worldwide, there is an evident increase in the incidence and accordingly in the prevalence of obesity. Current estimates postulate that the incidence of obesity will reach about 40% of the adult population by the year 2030. Importantly, developing countries do not seem to be immune against this epidemic. Accordingly, the worldwide performance of bariatric procedures is showing a corresponding yearly increase. Recent procedures such as sleeve gastrectomy are currently replacing old standard techniques. The increase in bariatric surgery numbers is unfortunately associated with complications that cannot be under estimated and that have been reported with all procedures. That is why timely diagnosis and management of these complications is an integral part of bariatric practice. Complications or (failures) can be broadly divided in early and late complications. Although readily reported, failure does not have a standardized definition. Gastric band has a special foreign body-associated nature and will therefore be separately discussed.

Acute failures or complications can be detected through reliable clinical symptoms and signs summarized in this chapter. Radiological studies and diagnostic laparoscopy are essential diagnostic and therapeutic tools.

Late complications or failures will be thoroughly discussed. Standardized techniques play the main role in the diagnosis of failure after bariatric intervention. These techniques can be implemented in all procedures. All these techniques will be discussed with their possible pros and cons. Diagnostic techniques include: radiological studies, endoscopy and diagnostic laparoscopy. Radiological studies include for example contrast-enhanced upper GI series, computed tomography and three-dimensional tomographic reconstructions. The role of endoscopy and diagnostic laparoscopy will also be highlighted.

INTRODUCTION

In 2005, 23.2% (937 million) of the world's adult population was overweight, and 9.8% (396 million) was obese. According to current projections, from 2005 to 2030 the number of overweight individuals will increase by 44%, to reach a total of 2.16 billion, corresponding to 38% of the world's adult population [1]. During the same interval, the number of obese individuals will increase by 45% to reach a total of 1.12 billion (20% of the world's adult population). In 2005, the prevalence of overweight was higher in economically developed countries compared to developing countries (35.2 vs 19.6%). Similarly, the prevalence of obesity was higher in developed countries compared to developing ones (20.3 vs 6.7%). However, growth in population size, aging, and urbanization of lifestyle will all contribute to an epidemic of overweight and obesity in developing regions in the next few decades [1]. This overwhelming increase in the prevalence of morbid obesity with its associated comorbidities pushed institutions worldwide to search for new minimally invasive modalities to face this epidemic. Over the past years, standard procedures like biliopancreatic diversion (BPD), duodenal switch (DS), gastric banding (LAGB), and Roux-en-Y gastric bypass (RYGB) established their position in the armamentarium of bariatric procedures. Other procedures such as sleeve gastrectomy and mini-gastric bypass are also partially replacing old standard procedures. More recently, newer surgical as well as endoscopic bariatric procedures started to compete with these standard procedures.

However, this increasing number of performed bariatric interventions does not come without complications, either acute early complications or late complications (failures) [2]. Unsatisfactory gastrointestinal manifestations were reported in 16.9% of patients who underwent RYGB, 7.8% of LAGB and 37.7% of BPD patients [2]. Reflux was reported by 10.9% of RYGB, and 4.7% of LASGB patients. Stomal stenosis was present in 4.6% of RYBG patients. Even sleeve gastrectomy, although one of the most recent procedures, suffers failures and complications as reported in many reviews [3, 4]. These complications attributed to bariatric interventions may be indications for operative revisions. In addition to these (anatomical) failures, another very important cause of failure indicating revision is weight gain after bariatric intervention. Some reports postulated that the most common cause for revision after a bariatric intervention is weight regain or insufficient primary weight loss after the intervention [5, 6]. Gagner reported that weight regain was the main cause of re-operation in about 90% of patients in his series [6]. The consideration of an intervention as failing needs

an adequate definition and a standardized diagnostic approach in order to correctly diagnose and then treat a failure when it occurs.

DEFINITION OF A FAILED BARIATRIC PROCEDURE

Controversy exists regarding the definition of a failed bariatric procedure. The wide spectrum of bariatric procedures performed worldwide and the lack of standardized criteria to define success or satisfactory outcome following a procedure plays a role. Another factor is the variation in the expected weight loss results following each procedure. Baltasar in a recent meta-analysis proposed that sleeve gastrectomy achieves the greatest mean BMI reduction (12-17 units) while gastric banding produces the least satisfactory outcome in terms of weight loss [7].

Another factor leading to the lack of definition of failure is the indication for revision after a (possibly) failed procedure. Failure or revision after most procedures is mainly due to inadequate weight loss. In the specific field of LAGB migration or slippage are important indications contributing to the consideration of gastric band as a (failed) procedure. This issue has been addressed in a recent systematic review by Mann and his colleagues [8]. Although Body Mass Index Loss is the most accurate interpretation tool for a successful or a failed procedure, still other indices are being used by other authors, for example percentage of total body weight, or change in BMI [8, 9].

The most frequent cited definition for failure after bariatric surgery as reported by Mann et al. was: <50% of excess weight lost (EWL), with or without residual BMI of greater than 35 kg/m², at 18 months post-operation.

The second most frequently cited definition was: <25% of excess weight lost (without a time-frame specified). However, in all the reviewed studies, there was surprisingly no comment on the effect of the primary procedure on the associated metabolic status of the patient. Consequently, remission or persistence of the associated primary metabolic impairment (diabetes and hypertension in the first place) was not listed as factor in assessing whether this procedure was successful or failed.

Additionally, most of the reviewed studies failed to report the selection criteria for failure. In our opinion, factors such as patient dissatisfaction with the procedure, food intolerance, and impairment of a healthy life style should also be part of the consideration of the procedure as a failed procedure.

In summary, a consensus for standardization of the definition of failure after bariatric procedure is still lacking.

SPECTRUM OF FAILURE OF A BARIATRIC PROCEDURE

A pitfall in most currently implemented definitions for a failed procedure is, in our opinion, the concentration on a long-term failure, and ignoring the acute or short-term failure. A failed procedure is also a procedure which can, in the early post-operative course, be associated with complications. Accordingly, early leakage or bleeding should also be counted as acute failures and should be timely and thoroughly diagnosed and accordingly managed.

Hence, we would like to classify failures broadly as: acute failures (can also be referred to as: acute complications) and long-term failures.

ACUTE FAILURE, DIAGNOSIS AND POSTULATED ALGORITHM (FOR ALL PROCEDURES OTHER THAN GASTRIC BANDING)

To be considered successful a bariatric intervention requires thorough understanding of the associated anatomical and physiological changes. Consequently it is preferably performed by a highly experienced team, that can diagnose and timely manage any deviation from the normal postoperative course. Otherwise, potentially devastating outcomes may occur. Recent data from the USA have reported postoperative complication rates ranging between 2.2-10.8 percent [10-12]. Retrospective analysis of our unit's data revealed an early postoperative morbidity rate of 7.1 percent [13].

Early postoperative failure includes, primarily, leakage and bleeding. In order to prevent and timely manage these events, a triad of adequate preoperative preparation, adoption of standardized operative technique and meticulous postoperative care is strongly recommended. During the early postoperative phase, persistent unexplained tachycardia of more than 100 beats/min, fever ($\geq 38.5^{\circ}\text{C}$), abdominal pain, tachypnea (>20 breaths/min) or decreased urinary output despite good hydration must induce a high index of suspicion. Laboratory findings of C-reactive protein (CRP) >150 mg/L, leukocytosis $>11,000$ cells/ml or a drop in plasma hemoglobin of more than 2 gram/dl also suggest the development of complications.

We recommend CRP level and complete blood count to be routinely checked on the first and fifth postoperative day. Diagnostic radiological and endoscopic tools should also be readily available but they are not routinely used in uncomplicated cases. In our center, all patients are discharged on the fifth postoperative day, as long as the postoperative course is smooth. Our experience suggests that postoperative hospital stay of up to five days ensures adequate perioperative patient assessment, unless postoperative complications necessitating a prolonged hospital stay are encountered.

Accurate diagnosis and timely management of acute failure of a bariatric intervention can be highly challenging. Particular care must be given to this high-risk patient group, where results of laboratory parameters may be misleading. Reliable clinical evaluation and interpretation of radiological studies pose another challenge. Thus, diagnosis and management of post-operative complications require an integrated teamwork approach that analyzes the triad of clinical suspicion, altered laboratory profile and abnormal radiological studies. More importantly, to date, we lack a consensus for sound management of those complications.

HOW TO DIAGNOSE A POSSIBLE EARLY COMPLICATION?

1. Laboratory Parameters

Routine postoperative check of patient's laboratory profile (full blood count and CRP) should be a standard practice. Any deviation from the normal values should be strictly

monitored. CRP and leukocyte count play a major role in the early detection of postoperative complications, especially staple line disruption and leakage [14]. Analysis of our data showed that elevated CRP and leukocytosis were detected in 18 patients (36.5 percent) out of 49 patients and 31 patients (47%) out of 66 patients with early complications after RYGB and sleeve gastrectomy respectively, including 19 patients (86.3%) and 12 patients (100 percent) who developed early postoperative leakage after those procedures [13].

Postoperative check of hemoglobin level is also mandatory. A drop of more than two grams/dl should warrant further work up, especially if combined with tachycardia, evidence of gastrointestinal bleeding or excessive bloody drain effluent.

2. Clinical Symptoms and Signs

Abdominal pain, nausea and vomiting requiring excessive analgesic or antiemetic treatment should raise the suspicion of possible complications. Hypotension, tachycardia, fever, tachypnea, dyspnea, low urinary output and abnormal color or increased volume of drain effluent should also be handled with a high index of suspicion [15]. Additionally, hematemesis or melena raise the suspicion of staple line bleeding. To date, the sensitivity and specificity of these parameters have not been well studied. Tachycardia seems to be correlated with the highest sensitivity and specificity amongst the other parameters [16, 17]. In our center, tachycardia was found in five patients (42%) and seven patients (37%) who developed early post-operative leakage and bleeding respectively [13].

3. Radiological Studies

Extravasation of gastrointestinal contents can be diagnosed radiologically by contrast-enhanced computed tomography (CT) scans with oral contrast (Figure 1a) or by gastrograffin swallow studies (Figure 1b).

The presence of an abscess cavity, air foci (Figure 1a) in the vicinity of the operative field or stranding in the mesentery on CT scans raise the possibility of leakage. Pleural effusion or pneumonia may also be suggestive of an underlying leak [18]. Intra- as well as extra-luminal bleeding can be diagnosed by CT scans. [19, 20]. The same applies to abdominal wall bleeding and intraoperatively inflicted solid organ injury.

Some authors perform routine postoperative gastrograffin upper GI series for all their patients due to simplicity and relatively low cost of the procedure [21]. Negative studies should however not mislead the surgeon in the presence of a strong clinical suspicion [15]. Mittermair et al. [22] reported complete inadequacy of gastrograffin series to detect leakages in their patients. Such data together with the radiation exposure accompanying these diagnostic modalities questions the necessity of their routine postoperative use.

(a)

(b)

Figure 1a,b. Extravasation of gastrointestinal contents can be diagnosed radiologically by contrast-enhanced computed tomography (CT) scans with oral contrast (a) or gastrografin swallow studies (b).

4. Diagnostic Laparoscopy (DL)

DL is the most reliable tool to confirm or rule out serious early postoperative issues including leakage and extra-luminal bleeding in patients with suspicious clinical, laboratory or radiological findings.

In our personal series, we have observed a 100% specificity for DL in 23 patients with complicated sleeve gastrectomy: DL confirmed complicated post-LSG course (13 patients with bleeding, nine with leakage and one with trocar-site hernia). This observation should be compared with the findings with RYGB: a specificity of only 70 percent in 33 patients with suspected complications. DL confirmed complications suspected by routine postoperative check in only 23 patients (12 patients with leakage, seven with bleeding, three with trocar site hernia, and one with small bowel obstruction) whereas it was negative in 10 patients (Table 1).

Table 1. Value of diagnostic laparoscopy (DL) in patients with a suspicious (*) post-operative course after LSG vs. LRYGB

First detected indication for DL	LSG N=23		LRYGB N=33	
	Diagnosis confirmed by positive DL	Negative DL	Diagnosis confirmed by positive DL	Negative DL
Elevated CRP	Leakage: 7	0	Leakage: 9 Trocar site hernia: 2	4
Tachycardia	Bleeding: 9 Leakage: 1	0	Bleeding: 6 Leakage: 3	4
Abdominal pain	Bleeding: 3 Trocar site hernia: 1	0	Bleeding: 1 Trocar site hernia: 1 SBO: 1	2
Suspicious CT scan	Bleeding: 1 Leakage: 1	0		0
Total number (%)	23 (100%) (p<0.05)	0 (0%)	23 (70%)	10 (30%)

LRYGB: laparoscopic Roux-en-Y gastric bypass, SBO: small bowel obstruction.

Values refer to number of patients in whom DL was done and confirmed or excluded a suspected acute post-LSG complication.

* Suspicious means: Persistent unexplained tachycardia of more than 100 beats/min, fever (≥ 38.5 C), a more than routinely-encountered post-operative abdominal pain, tachypnea (>20 breaths/min), or decreased urinary output despite good hydration, C-reactive protein (CRP) >150 mg/l, leukocytosis $>11,000$ cells/ μ l or a suspicious CT scan.

The discrepancy between RYGB and sleeve gastrectomy may be attributed to the fact that DL can miss some complications such as transient internal herniation, twisted gastro-jejunal or entero-enteral anastomotic reconstruction, intussusception or anastomotic ulcer post-RYGB. These factors that can lead to transient deviation from normal post-RYGB course are not encountered after LSG. The results are currently under further analysis for future publication. The incidence of bleeding after obesity surgery ranges from 0.6 to 4 percent [23, 24]. Stapling through highly vascular tissues can be followed by considerable amount of intra- as well as extra-luminal (intra-peritoneal) bleeding. Bleeding should be controlled by surgical intervention (hematoma evacuation, over-sewing, and drainage) when patients are hemodynamically unstable. In hemodynamically stable patients, we usually resort to conservative methods with fluid resuscitation, blood transfusion (if necessary) and careful observation. We propose the following algorithm (Algorithm 1) for possible diagnosis and management of acute failures after bariatric intervention.

LATE FAILURE AFTER BARIATRIC INTERVENTION; SPECTRUM OF DIAGNOSTIC MODALITIES

After briefly discussing the acute failure of a bariatric procedure, we would like to address the long-term failure of a bariatric procedure, which is a failure occurring after an uneventful early post-operative phase. All bariatric procedures can be subjected to long-term failure.

Algorithm 1. Management of patients with suspected acute leakage after bariatric intervention.

In our opinion LAGB should be separately discussed because of the specific nature of this foreign body-associated procedure. In addition to the common causes of long-term failures encountered with other procedures (weight regain, reflux, hiatal herniation, ulceration,.....) and urgent band-related conditions (gastric perforation, volvulus, abscess formation,.....), LAGB can cause two special conditions or causes of failure, namely: band slippage and band migration.

Diagnosis of Band Slippage

Band slippage is encountered in 4-13% of patients [25]. Patients with slipped band usually present with manifest upper abdominal pain and acute upper obstructive manifestation. If neglected these can progress to gastric gangrene by strangulation of the

blood supply of the pouch. Band slippage is usually an acute condition, and should be timely diagnosed and properly managed.

Band slippage is often recognized on gastrograffin upper abdominal series. The slipped band tends to be more horizontally placed [26]. Through the weight of the herniated stomach, the anterior and posterior band margins are no longer opposed and give the so called O sign [27]. Because of the progressive obstruction and strangulation, an air-fluid level may appear in the proximal gastric pouch.

Algorithm 2. How to manage a failed band.

Diagnosis of Band Erosion

Band erosion is usually a gradual process that can progress from incomplete to complete intra luminal band migration. Band migration usually presents with vague manifestations, including loss of restriction (with possible weight gain), upper abdominal pain and port site pain or port site infection. Band erosion is typically detected by gastroscopy. A systematic review of band erosion in 15,775 patients revealed 231 cases of erosion (1.46%) in 15,775 all detected by gastroscopy [28]. This experience should not understate the role of radiological

interventions in the diagnosis of this event. In fluoroscopic series, a leak of contrast around the eroding location of the band can be detected. CT scans can also detect a completely migrating band, with more certainty than incomplete erosion [29].

Port-Related Complications

Two important port-related complications are port inversion and tubing defect or disconnection. Port displacement can be readily detected in abdominal radiographs. Tubing system defect or disconnection can be diagnosed by water soluble contrast material injection in the port system.

We propose an algorithm for rapid assessment and diagnosis of gastric band failures (algorithm 2)

RADIOLOGICAL DIAGNOSTIC TOOLS FOR A FAILED BARIATRIC INTERVENTION

Fluoroscopy (Upper GI Series)

Water-soluble contrast upper GI series have commonly been used to show the pathway constructed by a bariatric procedure, be it restrictive or malabsorptive. In sleeve gastrectomy, the currently most commonly performed restrictive procedure, different patterns of the residual stomach have been described by Werquin et al. [30]: a tubular pattern (66%) with a uniform caliber, the superior pouch pattern (26%, with a wide superior component of the retained fundus that gradually fills), the inferior pouch pattern (8%, with a wide residual distal component), the superior-inferior pouch pattern (both proximal and distal pouches), the pseudodiverticular pattern with a diverticular dilatation of the lesser curve. Other rare patterns, such as the corkscrew have also been reported [31].

Long-term failure of sleeve gastrectomy can be seen in fluoroscopic upper GI series, where gastric dilatation or stenosis can be diagnosed. Gastric dilatation is usually suspected in fluoroscopy by loss of the normal tubular pattern of the sleeve and pouch enlargement. Stenosis can be readily seen by impaired distal contrast flow, and may be associated with proximal gastric dilatation (Figure 2), gastro-oesophageal reflux and hiatal herniation.

Upper GI series play also a significant role in failed malabsorptive procedures. Assessment of the proximal pouch, the alimentary limb and the site of the gastro-enterostomy can be accomplished by fluoroscopic series. Gastric pouch size can be readily assessed by upper GI series, especially if compared with immediate post-operative series. Shah et al. [32] described that the size of the gastric pouch after RYGB should be the same as that of lower thoracic or lumbar vertebral body.

Upper GI series by their dynamic nature allow to demonstrate stenosis of the gastroenterostomy. Pouch distension and delayed passage of contrast through a smooth narrowing are highly suggestive for this condition [32].

Although not typically diagnosed in upper GI series, a stenosis of the entero-enteral (JJ) anastomosis can also be shown on these series. If stenosis is associated with significant stasis

at the pancreaticobiliary limb, symptoms may include pancreatitis and biliary stasis. The stasis may be severe enough to induce gastrogastic fistulation or rupture (blow out) in acute cases. This situation may be diagnosed on dynamic series by stasis of contrast flow, retrograde passage in the biliopancreatic limb or reflux in the alimentary limb. Plain abdominal films may also show fluid level formation.

Figure 2. Stenosis can be associated with proximal gastric dilatation.

In malabsorptive procedures a specific cause of failure is blind loop formation. This formed sac acts as a reservoir or a second stomach, which overtime may lead to loss of the restrictive element of the procedure. Late evacuation of its contents is in our opinion another cause for late dumping symptoms. Additionally, recurrent abdominal colics and bacterial overgrowth may be associated with blind loop sac formation.

Marginal ulcers developing at the gastroenterostomy site are an important cause of failure after bariatric procedures, usually presenting with vague upper abdominal complaints (Pain, nausea, vomiting, etc.). Smoking and chronic acid exposure are possible precipitating factors. In upper GI series these ulcers can be seen as ulcer niches at the anastomosis site or in the proximal part of the alimentary limb [33].

Another condition that may occur after bypass procedures is internal herniation, a situation linked tot the creation of peritoneal defects. This condition can also be detected in GI series when small bowel limbs containing contrast in their lumens are seen within the hernia space [34, 35].

Dynamic upper GI series may also help in the diagnosis of gastro-gastric fistulation, when contrast flows in the distal pouch.

Despite the value of fluoroscopy in obesity practice, practical difficulty in performing the study may influence interpretation [36]. Practical difficulties include for example fluoroscopy table weight limit. Most currently used static tables tolerate not more than 550 pounds (400 pounds for movable tables). However, larger capacity systems are now available with weight limits up to 600 pounds for static tables and 500 pounds for movable tables. The problem of

poor interpretation can be overcome by performing the study in supine position with lateral spread of weight, leading to decreased thickness of abdominal wall tissues and accordingly better interpretation of the study with a lower dose of radiation. Another issue is the distance between the table and the radiation source, which typically ranges from 45 to 49 cm, and reaches in recent devices up to 60 cm. Performing the study in supine position may allow a better accommodation of the patient in the device. A third problem is the width of the table, which if insufficiently wide, may lead to patient instability during the examination. A fourth problem is the need for a higher dose of radiation to penetrate through a relatively thicker abdominal wall.

In fluoroscopic diagnostic studies we prefer to use water soluble contrast (Gastrograffin). This avoids the risk of barium induced peritonitis and at the risk of impaction at any stenotic site. An important precaution point is to allow for a reasonable period of fasting after gastrograffin intake in cases where an operation is indicated. Alternatively, gastric decompression should be tried. Several reports documented the irritating hypertonic effect of gastrograffin on bronchial epithelium, and the occurrence of marked pulmonary oedema and even death in case of aspiration [37].

Apart from 3D gastric pouchography, which is of utmost importance in follow-up of all bariatric interventions, conventional abdominal CT scans (enhanced by oral and intravenous contrast) are also of value in assessing failure or complications after bariatric interventions. Because we are focusing in this chapter on long-term failures after bariatric interventions we will not discuss the major role of CT scans in assessing acute complications after surgical interventions. Instead, we will mention some possible causes of failure, that can be diagnosed on routine CT scans.

Recurrent weight gain or insufficient weight loss can result from enlargement of the constructed pouch and/or the alimentary limb. This can be easily detected on abdominal CT scans. After sleeve gastrectomy, loss of the normal tubular shape of the constructed pouch denotes a possible cause of insufficient weight loss. After malabsorptive procedures, pouch enlargement, distension of the alimentary limb, or widening of the anastomosis play a similar role.

Measuring the diameter of the gastroenterostomy during examination should be a routine part of interpretation of CT scans in patients who underwent malabsorptive bariatric interventions. In these scans, administration of an oral contrast material just prior to the examination helps to differentiate the gastric pouch, gastroenterostomy and alimentary limb (which are opacified) from the biliopancreatic limb and enteroenterostomy (non opacified). This is essential for adequate interpretation of the cause of failure and also for detecting potential events like internal herniation. Distention of the gastric pouch and collapse of the distal pouch are also important features. The normal peristaltic movements of the biliopancreatic limb protects from retrograde passage of contrast material or gases in this limb [29, 38]. Through oral contrast intake, conditions such as gastrogastic fistulation can be detected by abnormal flow of contrast in the distal gastric pouch. Similarly, with adequate localization of the gastric pouch and alimentary limb, blind loop formation (also at the site of the enteroenterostomy) may be seen. Although not typically diagnosed, marginal ulcerations have been reported to be detected on CT abdominal scans [39].

THREE DIMENSIONAL CT ASSESSMENT

A corner stone in accurate assessment of failure after bariatric intervention is the proper outlining of anatomical changes in the gastro-intestinal tract, which allows to choose the best management or revisional modality. Previous studies reported that accurate assessment of pouch size enables the surgeon to design the best strategy and perform the best available intervention [40]. Here, we think that 3D pouch construction provides the best aid to the treating team.

Despite reports that endoscopy, upper GI series and CT scans are the most commonly used assessment modalities [41-45], we believe that they don't offer sufficient data. Endoscopy is to some extent operator-dependent and routine CT is of a higher value in the evaluation of acute complications. Endoscopy is more invasive and is not free of complications. Moreover, insufflation of air during endoscopy may lead to over-distension of the gastric pouch [40]. The classical upper GI series can be useful in providing approximative data for pouch volumes. Langer and his colleagues postulated that a sleeve wider than 4 cm is considered to be dilated, but they did not estimate the sleeve volumes [46].

Three dimensional CT gastric reconstruction (together with alimentary limb reconstruction) represents in our opinion the best investigative modality for pouch and alimentary limb. Based on our experience, we affirm that this modality of investigation gives the most accurate reconstruction of the actual intra-abdominal anatomy. Sets required for this investigative modality should be an integral part of any center practicing obesity surgery.

Although there were reports [47] comparing the accuracy of pouch measurements after gastric bypass using gastroscopic assessment versus those using 3D pouchography did not find statistically significant difference between both measurements, we still stress on the superior value of 3D pouchography. As mentioned, interpretation of endoscopic findings can be operator dependent. Many authors support our opinion regarding the value of 3D gastric pouchography [48].

Technically, 3D pouchography entails drinking a powder or effervescent granules diluted with water after overnight fasting. Ingestion allows stomach distension with air. This distension helps in obtaining an actual picture for the current gastric (and alimentary limb) anatomy. Addition of a spasmolytic agent is indicated. Some authors prefer glucagon [47], others tend to use Buscopan® [40]. Thin slice scans (1 mm) are taken and three dimensional volume-rendering images created in a 3D workstation. The modality is described in different techniques using different contrast agents. [40, 47, 48] Some authors tend to use iodine containing contrast agents [40], others prefer effervescent granules without the use of iodine-containing oral contrast agents [47].

Some authors [47] resort to 3D pouchography to obtain base line data for future comparison in patients with non-satisfactory results after bariatric intervention. Through this modality a large and sufficient deal of information can be available which, if properly analyzed, usually allows for the best intervention to overcome the encountered failure after a bariatric intervention. A large pouch can be easily assessed (Figure 3).

Other abnormalities such as loop formation, a wide gastroenterostomy and a twisted pouch (Figure 4) can be readily diagnosed [40]. In addition, hiatal herniation, a common cause for complaints after bariatric intervention can be adequately diagnosed (Figure 5).

Other less readily detected pathologies, e.g. gastro-gastric fistulation are also readily seen in 3D pouchographies. Reports from different centers on cases of fistulation that failed to be diagnosed despite several gastroscopies and upper GI series have been published [40].

Moreover, computed tomography with 3D imaging has been shown to be of reasonable value in patients with previous gastric banding, because it allows to delineate the entire band, location and orientation, as well as related complications such as erosion, slippage and infection. Port-related complications may also be detected [49].

A possible limitation of this modality is its inherent radiation exposure [50], although low dose exposure with a highly preserved quality can be achieved in recent stations [48, 51]. Some assume that the radiation dose used in 3D CT imaging does not exceed the radiation dose in conventional CT scans [48].

Figure 3. A large pouch after sleeve gastrectomy seen on CT pouchography.

Figure 4. A twisted pouch after sleeve gastrectomy.

Figure 5. Hiatal herniation, a common cause for complaints after bariatric intervention can be adequately diagnosed on CT pouchography.

Blanchet et al. mentioned additional limitations of this technique [48] i.e., the need for a recently equipped station, and the learning curve required for performing the study and interpreting its findings (although the latter usually does not exceed 10 minutes after achieving an adequate learning curve). Inadequate fasting or failure of adequate oral intake of the contrast agent [40], leads to incomplete distension of the pouch and inadequate interpretation of the results.

ROLE OF ENDOSCOPY IN FOLLOW-UP AND DETECTION OF FAILURES OR COMPLICATIONS AFTER BARIATRIC INTERVENTIONS

Endoscopy plays a major role in the bariatric field in that it allows evaluation of symptoms attributed to complications or failures after surgery. In an analysis of more than 7,000 restrictive and malabsorptive procedures 4 main complications were reported after restrictive procedures; pouch or stoma dilatation (2.4%), stomal stenosis (2.2%), staple line failure (1.5%) and stomach erosions (1.2%). These complications were also reported after malabsorptive procedures with incidences of 0.47%, 2.7%, 5.9% and 1.2% respectively. These figures denote the importance of follow-up endoscopy in assessing failures and complications after bariatric interventions [52]. That is why we recommend a scheduled follow-up endoscopy regimen after bariatric interventions. The diagnostic spectrum of gastroscopy in patients with failed bariatric surgery is very broad and better to be illustrated based upon which procedure is performed and its possible causes of failure or complications.

Follow-Up Endoscopy after Roux-En-Y Gastric Bypass

Patients with nausea, vomiting or dysphagia after RYGB should have a gastroscopic evaluation to rule out conditions like marginal ulceration in 27-52% of patients followed by stomal stenosis in 4 -39% [53, 54, 55].

Stomal Stenosis

An anastomosis is considered stenotic if the normal 9.5 mm endoscope cannot readily bypass it [56]. Stenosis has a reported incidence of 5-12% after LRYGB [57, 58]. Possible underlying factors for a stenotic gastrojejunostomy include local ischemia, the use of a circular stapler and local inflammation (by smoking for example) [56].

In case of stenosis in the presence of active marginal ulceration ulcer treatment should be initiated prior to dilatation of the stenosis to avoid inadvertent perforation during the dilatation sessions [56]. An intended diameter of dilatation to avoid symptomatic recurrence is 15 mm [59]. An important point to be considered here is to adequately assess the proximal part of the alimentary limb to rule out any associated pathology or active ulceration.

Endoscopic dilatation can be safely started 4 weeks post-operatively [59, 60] and is usually performed using balloon dilatation through a bougie passed over a guide wire. Guide wire guidance is essential when a bougie cannot be readily passed through a stenotic stoma [56]. Torsion, angulation of the stoma and marginal ulceration are all underlying factor for failed dilatation.

Marginal Ulceration

This condition is reported to vary in incidence from 0.6-16% [45]. Marginal ulcers are asymptomatic in more than 20% of cases [58]. Ulcer development is limited to the intestinal side of the anastomosis [56].

An important predisposing factor for marginal ulceration and pouch inflammation is *H.Pylori* infection. Although not highly sensitive, mucosal biopsies should be taken prior to and during every follow-up endoscopic session after RYGB, and the same applies to all bariatric interventions. A proved infection should be thoroughly treated and follow-up endoscopy after eradication is a routine practice in our patients.

Other factors than *H. Pylori* infection have been strongly linked to marginal ulceration. These factors may be either intrinsic or extrinsic. The former include pouch acid production, pouch ischemia and gastrogastic fistula due to retrograde passage of acid produced from the distal pouch into the constructed pouch and subsequently over the site of the anastomosis. The latter include smoking and alcohol consumption.

Pouch and Stomal Dilatation and Blind Loop Formation

This triad represents an important cause of failure after RYGB. In this case failure is determined by insufficient weight loss or weight gain. Through any of those three causes, an abnormally large amount of food will be ingested and rapidly dumped distally. This can simply be explained by loss of restriction. During endoscopy, length of the pouch (distance between the gastro-oesophageal junction and the stoma) can be readily measured. Despite the

fact that the diameter of the stoma can be assessed by experience of the endoscopist, it cannot be actually measured. Thanks to the advances in interventional endoscopic techniques, the spectrum of endoscopic applications exceeds the diagnostic level and reaches the therapeutic level. Techniques as the endoscopic overstretch are currently practiced in our clinic, but results are still in the evaluation phase.

Gastro Gastric Fistulation

An important cause of failure after RYGB is the formation of a gastrogastic fistula. A channel is gradually formed between the proximal and distal gastric pouches. This condition has two effects. First, the restrictive effect of RYGB is lost due to the passage of food stuffs from the proximal pouch into the distal pouch which causes the patients to tolerate larger volumes of meals. Second, the retrograde passage of acid from the distal into the proximal pouch results in exaggerated effect of gastric acid on the constructed stoma, with consequent oedema, ulceration and stenosis. This event is not easily found during routine endoscopy performed by non-experienced personnel. As previously mentioned, pouchography plays a major role here. Still, besides its possible therapeutic role, endoscopy can assess this situation, and get access to the distal stomach pouch.

Follow-Up Endoscopy after Sleeve Gastrectomy: (Figure 6)

Figure 6. Follow-up endoscopy after sleeve gastrectomy showing a gastric fistula.

Stenosis of the Sleeve

Although uncommon, stenosis is a serious complication after sleeve construction. We experienced cases with severe nutritional impairment due to sleeve stenosis, up to Beri Beri and Wernicke's encephalopathy. Stenosis is most common at the incisura angularis. In our opinion, gastroscopy can help in evaluation of a stenotic sleeve. It is noteworthy that the stenotic segment can be overlooked when the endoscope, when it crosses the stenosis thanks

to its mere weight. This is why we recommend pouchography for the accurate assessment of the stenotic segment before ruling out sleeve stenosis. (Figures 7a,b,c)

Figures 7a,b,c. Sleeve stenosis as seen on CT pouchography.

Sleeve Dilatation

Long-term results after sleeve gastrectomy are not universally satisfactory in terms of weight loss and weight regain has been reported in 75% of the cases [61]. This finding has been correlated with increased sleeve volume. Consequently assessment of the sleeve volume in late follow-up sessions is of utmost importance. Patients presenting for evaluation of

weight regain or non-satisfactory weight loss undergo a standardized assessment that mainly includes endoscopic assessment followed by pouchography.

During endoscopy, a wide sleeve, allowing swift retroflexion or inversion of the gastroscope, usually indicates an increased sleeve volume. Accurate measurement of the sleeve volume and shape however cannot be accomplished by endoscopy. The full assessment usually proceeds to pouchography to delineate the new sleeve shape.

Follow-Up Procedures after Malabsorptive Procedures (Biliopancreatic Diversion, BPD)

As for RYGB, pouch assessment (whether a large pouch of 200-500 ml size in BDP Scopinaro or a tubular sleeve in duodenal switch) and stomal inspection can be endoscopically performed. Biopsies from a marginal ulcer or for detection of *H. Pylori* gastritis, or from ileal mucosa can be easily achieved. Conditions involving stomal stenosis, pouch dilatation or blind loop formation are very amenable.

Follow-Up Procedures after Vertical Banded Gastroplasty

Vertical banded gastroplasty is no longer a common bariatric practice. This procedure remains interesting because of the common presentation of patients with history of vertical banded gastroplasty who suffer from problems related to the functional failure of this procedure. A high pressure created by a stenotic distally applied ring or mesh is cranially propagated. This leads to a common triad of presentations; gastro-oesophageal reflux, pouch enlargement (new stomach) and gastro-gastric fistula. The latter two phenomena are associated with loss of restriction with resultant weight gain. All these changes can be detected endoscopically. Again, the accurate volumetric assessment is better achieved by pouchography.

Follow-Up Procedures after Gastric Banding

At endoscopy a normally functioning non-complicated band in retroflexion appears as a belt surrounding the gastroscope. However, two important conditions have to be carefully assessed after gastric banding; band erosion and band slippage. We discussed before band slippage, a condition that as mentioned before is better assessed by upper GI series. Band erosion is also diagnosed by upper GI series, but endoscopy here seems to be a better diagnostic tool. Band erosion has been reported in rates ranging up to 2.8%. [62] Band erosion is a gradual process involving penetration of the tight band into the gastric wall. The blackish discoloration of the eroding segment is pathognomonic and is possibly due to the burning effect of gastric acid on this segment. Patients suffering from band erosion usually present with a gradual loss of the restricting effect of the gastric band. Sometimes the first manifestation of erosion is tenderness or infection of the port of the migrating band, due to ascending infection along the tubing system. Endoscopy can be both diagnostic and

therapeutic in these cases, as band extraction can be completed endoscopically provided more than 50% of the band circumference is eroding inside the stomach lumen [56].

Endoscopy and Hiatal Hernia after Bariatric Intervention

A commonly encountered event after bariatric intervention is hiatal herniation. Either this herniation was already present at the time of the primary intervention, or it developed by disappearance of the fat pad surrounding the cardia as a part of weight loss after bariatric surgery. This leads to the classical symptoms of hiatal herniation presenting as epigastric discomfort, dysphagia or reflux manifestations. Endoscopy has been broadly used in the diagnosis of this type of sliding hiatal herniation. Herniation can be assessed by one of two methods [63]: either by measuring the distance between the squamocolumnar transition and the diaphragmatic impression (usually considered when more than 3 cm), or by inspecting the impression of a patulous diaphragmatic sphincter by a retroflexed endoscope).

Endoscopy and Reflux Disease after Bariatric Intervention

Another important cause of failure or dissatisfaction after bariatric intervention is the development of gastroesophageal reflux disease. Patients usually present with typical manifestations including dull aching upper abdominal pain, heart burn, vomiting and dysphagia with in extreme cases reflux of gastric juice through the nose. We saw many cases presenting with intolerable reflux manifestations, mainly after sleeve gastrectomy. That is why diagnosis of gastro-esophageal reflux disease should be a routine part of follow-up after bariatric intervention. Differential diagnostic points include other medically-treatable causes (e.g.: *H. Pylori* induced gastritis and marginal ulceration, etc.). After ruling out all medical causes, and after failure of medical management of reflux, a surgical approach may be required, for example conversion of a sleeve into RYGB. The role of endoscopy in this condition should be respected. The presentation with the typical findings of reflux on endoscopy is diagnostic with a specificity of about 95% [64, 65].

Role of Diagnostic Laparoscopy in Assessment of Failure after Bariatric Intervention: (Figure 8A,B)

Laparoscopy constitutes one of the best diagnostic (and at the same time therapeutic) modalities. Some patients are presented with failures or complications after bariatric interventions that remain unexplained despite a full diagnostic work-up.

Conditions such as extensive adhesions, blind loop formation, twisted pouches or sleeves, herniations (whether internal or hiatal) may escape diagnosis by the routinely available techniques. This is a frequent event. In these patients, diagnostic laparoscopy gives the highest level of accuracy and offers at the same time a simultaneous therapeutic option. (See before also, the role of diagnostic laparoscopy in the assessment of acute failures after bariatric interventions)

Chapter 54

ADJUSTABLE GASTRIC BAND FAILURES

J. W. M. Greve*

Dutch Obesity Clinic South,
Department of Surgery, Zuyderland Medical Center Heerlen
and Orbis Medical Center Sittard, Heerlen, the Netherlands

ABSTRACT

The adjustable gastric band is a good treatment option but requires a strict follow up and good compliance of the patient. Despite good results failures do occur either due to technical failures or patient non-compliance. Failure can also be a result of band complications.

In many cases surgical revision is possible either by repositioning of the band or replacement of the band. A back on track program and band adjustments can also result in recovering an initial good result.

In case of band failure conversion to another technique is shown to be safe and effective. A good treatment strategy is based on the conclusions of a mandatory multidisciplinary team.

Failure of an initially successful band is rather a phase in a lifelong obesity treatment program and not a disqualification of the band as valid treatment option.

1. INTRODUCTION

In search for a safe and effective surgical treatment for morbid obesity the idea of an adjustable band was developed. As early as 1982 a first paper on adjustable gastric banding was published and mid eighties of the past century a workable device was constructed and used clinically [1, 2]. Laparoscopic placement made it a very successful and frequently used device (Cadiere, Belachew) [3, 4]. Many types of the adjustable silicone gastric band (ASGB) have been developed over the years. The most important improvement was a change from low volume high-pressure bands to high volume low-pressure bands, which reduced the risk

* Corresponding Author's Email: j.greve@atriummc.nl.

of erosion significantly. Placement of the band in the early days was peri-gastric creating the retro gastric tunnel by dissecting at the lesser curve of the stomach. This technique had a significant erosion rate probably due to micro lesions of the stomach wall. Moreover due to placement through the lesser sac with a relatively large pouch slippage and pouch dilation were a frequent problem. These problems were significantly reduced by introduction of the pars flaccida technique [5].

Over the years it has been shown that follow up is crucial in a successful treatment program in patients with an adjustable gastric band. There is a significant correlation between frequency of follow up and weight loss as was shown by Ren and colleagues [6]. Several algorithms have been proposed to improve outcome, in particular on when and how to adjust the band. The green zone concept by O'Brien based on clinical parameters is the most effective, but other options are available such as adjustments based on balloon pressure as proposed by Fried [7]. When all criteria are fulfilled (correct placement, correct type of band and an optimal follow up program) good long term results (>5 years) can be achieved that are comparable to the gastric bypass [8, 9].

Currently however, most bariatric surgeons no longer consider the adjustable band as a viable treatment option. Long term results from early series with inferior band types and poor follow up programs show very poor results with a high percentage of revisions and band removals and few patients with sufficient long-term weight loss. Poor results and the introduction of "easy, no worry, procedures" such as the gastric sleeve resection has resulted in dramatic reduction of band placements, partly under pressure of the public opinion. Nevertheless with a good patient selection and a good follow up program the adjustable band is still a very valid treatment option.

As all bariatric procedures the adjustable band is not flawless. Even in good programs problems may occur that need correction. Moreover more than 800,000 bands have been placed worldwide which means that, even with low failure rates, there will be a significant number of patients that may need a revision or conversion of the procedure.

2. BAND FAILURES

Failures of the band can be divided in several categories. Primary failures pertain to patients who never reach a desired weight loss, which can be due to a technical problem (high band position, large size of the band, malposition of the band, mechanical defect of the band etc.) or due to non-compliance of the patient (poor diet habits, failure to adhere to the follow program). A second category consists of the patients who had a successful weight loss but then regained weight. This can be due to a mechanical failure (band leakage, tubing or port disconnection, tubing breakage), slippage of the band or pouch dilation or changed dietary habits of the patient while some patients develop band intolerance. A third category consists of the patients with a band complication, a condition that often needs acute intervention. Examples are acute herniation of the stomach through the band, acute obstruction, erosion of the band, internal herniation of bowel around the tubing but also severe reflux and/or esophagus dilatation.

3. GENERAL CONSIDERATIONS IN REVISION OR CONVERSION

When a surgical procedure is required to improve the outcome of the patient this can either be a revision/correction of the current procedure (e.g., band reposition, band replacement, port revision etc.) or a conversion to a different type of procedure [10]. Reversal is in itself an easy procedure but should only be considered on explicit patient request or under rare circumstances. Just removing the band will without exception result in weight regain and loss of the positive effect on the co-morbidities. If a band is removed it is advisable to take down the entire plication (gastro-gastric sutures) in case the patient reconsiders and comes back for a new bariatric procedure.

In all patients careful evaluation by a multidisciplinary team including a dietician, psychologist and bariatric surgeon is mandatory. This may help to identify patients who have a deteriorated eating pattern or inappropriate life style changes. In these patients a “back on track” program and careful adjustment of the band may be sufficient. However multidisciplinary team evaluation can also assist in the decision on which strategy to follow when a revisional procedure or a conversion to another technique is required. Next to evaluation of patient behavior upper gastrointestinal X-ray and or endoscopy are required to detect technical failures or band complications. The final decision for an intervention should always be based on evaluation of all results by the multidisciplinary team.

4. PRIMARY FAILURE

Primary failure as a result of a technical failure should be evaluated carefully. In all patients dietary counseling is mandatory as well as evaluation of filling volume of the band. Life style modifications need to be recorded as well. Diagnosis based on these results is a multidisciplinary team effort. X-ray and or endoscopy are required to exclude a technical problem. If there is a band malfunction (leakage, band not closed) or malposition of the band (band not around the stomach) a revision of the band is required by either replacement of the band or repositioning. In case of a high band position (no stomach above the band, Figure 1C) successful reposition of the band is unlikely and conversion to another procedure is required.

Available options are Roux en Y gastric bypass (RYGB), sleeve gastrectomy (SG), biliopancreatic diversion (BPD), duodenal switch (DS) or omega loop gastric bypass. More recently some surgeons have added a gastric plication to the band but long term results are not available yet [11]. Conversion of a failed restrictive procedure to a new type of restrictive procedure is less likely to be successful. However, several authors have reported good outcomes of conversion to a SG. Nevertheless, in most series conversion to a RYGB is considered the gold standard and good outcomes are reported [10, 12]. Optionally conversion to RYGB can be done while leaving the band in place for future adjustments (adjustable banded RYGB) [13]. Although BPD and DS are feasible not many surgeons are in favor of this options [14, 15]. This is also true for the so called “Bandinaro” in which the band is left in place [9].

Figure 1. Upper GI X-ray of band related complications. A: posterior slippage with vertical band position. B: anterior slippage with horizontal band position. C: primary failure with high band position (no gastric pouch). D: acute herniation of the stomach through the band.

4.1. Conversion to Sleeve Gastrectomy

Since its introduction the nowadays very popular SG procedure is being used as rescue operation for the ASGB. It has been shown to be feasible and relatively safe although severe complications have been reported with a significant percentage of leaks and fistulas that are difficult to treat [16]. The procedure can be done in 1 or 2 stages with a lower reported complication rate in the latter strategy [17, 18]. Successful weight loss is reported ranging between 31-60 %EWL however there is an increased complication rate with leaks in up to 6% [10]. In a paper by the group of Rosenthal et al. comparing RYGB with SG after band it was found that in non-responders (primary failure) conversion to RYGB was more successful than SG [19].

4.2. Conversion to RYGB

Most reported series on treatment of a failing ASGB treat conversion to RYGB. In particular, in primary failures (non-responders) successful treatment is more likely with a bypass [19]. Similar to conversion to a SG a 2-stage procedure may be more safe but a large number of publications have shown the efficacy and safety of conversion to a RYGB in 1 stage [12]. Outcome after conversion to RYGB is comparable to the results of a primary RYGB with similar or slightly higher complication rates [12, 20].

4.3. Conversion to Adjustable Banded RYGB

Restriction is an important part of the working mechanism of a RYGB. Several studies have shown a benefit for a non-adjustable band placed around the pouch of the RYGB as reported by Fobi in open RYGB and more recently by Bessler in laparoscopic procedures [21, 22].

Furthermore, placement of an adjustable band around the gastric pouch of RYGB patients with weight regain was shown to be a valid option [23]. In patients with banded pouch after SAGB, all studies reported further weight loss, varying from 55.9%–94.2% excess body mass index loss (EBMIL) after 12–42 months of follow-up (Figure 2). With these considerations in mind a logical step was to leave the band in place when conversion to a RYGB was indicated, to prevent pouch dilation and to add the option for adjustments. Feasibility of this strategy has been demonstrated but larger studies with long term follow up are needed [13]. Potential problem with this treatment mode is that the band may add complications to a regular gastric bypass such as slippage, infection and erosion of the band. Most important is to protect the band from contact with the small bowel as was shown in the past with the adjustable RYGB.

Figure 2. Salvage of failing RYGB with an adjustable band on the pouch. Excess body mass index loss (%EBMIL) after revision. Values shown for follow-up (in months) after revisional surgery (t₀) [23].

This was a procedure in which the pouch above the band (allowing access to the remnant stomach by opening the band) was used to anastomose the jejunum to (Figure 3). This resulted in a high erosion rate into the small bowel and the procedure was abandoned after careful evaluation [24].

In conversion of a band to adjustable band RYGB the excluded stomach can be used to create a Nissen like plication distal to the band (Greve plication) to prevent slippage and avoid contact of the SAGB with the small bowel (Figure 4).

Figure 3. Functional or adjustable gastric bypass. A procedure with a high risk of band erosion to the small bowel [24].

Figure 4. In conversion of a band to adjustable RYGB the excluded stomach can be used to create a Nissen like plication distal to the band (Greve plication) to prevent slippage and contact of the SAGB with the small bowel.

5. SECONDARY FAILURE

Secondary failure is defined when patients who had an initial good weight loss and resolution of co-morbidities experience significant weight regain. Causes can be patient related (diet, life style) or due to a technical problem. Minor problems such as port dislocation or port disconnection are not discussed here, as the solution is simple. The majority of secondary failures are related to pouch dilation or band slippage. In early series pouch dilation or slippage was a frequent problem in up to 40% of the patients [25]. Introduction of the pars flaccida technique has significantly reduced the incidence of slippage to 6.5% and less [8, 25].

5.1. Failure Due to Patient Compliance or Due to Band Intolerance

In patients with insufficient follow up or incorrect band adjustments (too tight or not tight enough) a “back on track” program and proper adjustment of the band may be an option. In particular a too tight band will result in wrong eating habits.

These patients can develop reflux like symptoms and often are permanently hungry due to lack of satiety. Opening the band and re-education of the patient may work. However most patients will need a conversion to a different procedure. Options are discussed in subsection 4.

5.2. Mechanical Failure of the Band

Although the adjustable bands are made of durable silicone, technical failures can occur. Breakage or unlocking of the band will result in loss of restriction and weight regain. Another cause of loss of restriction is breakage of the tubing, which is often due to material fatigue. Inserting a connecting piece can fix breakage of the tubing but it is probably better to replace the band as is the case with a broken band. Leakage of the balloon can also occur. In particular in some of the older band types (Swedish band) a fold in the balloon could cause a perforation of the balloon at inflation.

5.3. Pouch Slippage or Dilation

Definition of slippage versus pouch dilation is difficult and not relevant for the treatment. After counseling by the multidisciplinary team and proper diagnosis by radiology initial treatment can be band deflation. If there is a spontaneous reposition gradual insufflation of the band can be attempted [26]. Failure of reposition after deflation or recurrence of slippage is an indication for band reposition in patients with good weight loss. Good results have been reported also on the long term with this policy [27, 28]. In the early days posterior slippage (band in a vertical position, Figure 1A) was a frequently encountered problem with the perigastric technique. Replacing the band using the pars flaccida approach can solve this issue. In the more common anterior slippage (band in a horizontal position, Figure 1B)

laparoscopic repositioning is in general successful. An important technical aspect is the release of all gastro-gastric sutures and the gastric plication all the way to His' angle. In most cases the band can be opened and re-used. After correction of the position, fixation of the band by plication of the fundus to the pouch with a minimum of 4 non-absorbable sutures is required. Symmetrical pouch dilation probably requires conversion to RYGB because successful repositioning is less likely [26].

5.4. Gastro-Esophageal Reflux (GERD)

Secondary GERD is usually a result of a too tight band with stasis and regurgitation of food into the esophagus. Opening the band may resolve this condition. In some patients a hiatal hernia may have developed de novo or was missed during band placement. Correction by closing the hiatus and repositioning of the pouch is an option [29]. However, in general in patients with severe reflux symptoms conversion to a RYGB with, if applicable, repair of the hiatal hernia is considered to be the best option [30].

6. BAND COMPLICATIONS AND TECHNICAL FAILURES

6.1. Revision after Band Erosion

Band erosion can be early or late. Early erosion is most likely due to a lesion of the stomach wall at insertion or a secondary infection of the band. Late erosion can be due to over-inflation of the band but often no clear explanation is found. Symptoms are upper abdominal pain, loss of restriction and sometimes the opposite, food intolerance. Fever may occur and inflammation around the port of the band is often a first symptom of band erosion. Diagnosis is confirmed by gastroscopy, followed by CT scan that can be helpful to identify a large inflammatory mass. Treatment strategy is manifold. Once the diagnosis is confirmed the band can be removed (endoscopically or surgically). Endoscopic band cutting tools can be used for endoscopic removal but in that situation the port of the band needs to be removed first [31].

Port removal is in general advised to prevent complications due to the tubing when the band migrates in total to the stomach with the port still attached. Surgical removal is the most used option, the laparoscopic approach being the preferred one. It is possible to immediately convert to another procedure such as repair of the gastric wall defect and placement of a new band or conversion to gastric bypass [32, 33]. Alternatively after removal of the band and closure of the defect a biliopancreatic diversion can be constructed in the same session, avoiding an anastomosis in an infected and inflamed area. However, in most cases band removal and revision some 3-6 month later is preferred.

When the patient benefited from successful weight loss with the band, re-banding may be attempted. After band erosion, conversion to RYGB is nevertheless preferred and, as mentioned before, long-term results are good. In fact a 2-stage procedure allows conversion to any type of bariatric procedure later on. A 1-stage conversion to SG or RYGB is not advised because of the high complication risk, in particular leakage.

6.2. Band Obstruction

Obstruction of the band may be due to a large food particle, a bezoar or may be due to acute herniation of the stomach (see below). Symptoms are food intolerance, inability to drink and regurgitation of saliva. Occlusion of the outlet can be solved by deflation of the band or by endoscopic removal of the foreign body or food particle. Bezoar is rare but can be more problematic and, if large, may even need surgical removal. Prevention by avoiding the ingestion of indigestible fibers (asparagus, oranges etc.) is key.

6.3. Acute Herniation of the Stomach

When a patient after ASGB develops sudden food intolerance and epigastric pain he/she should be considered an emergency. When a significant part of the stomach herniates through the band incarceration of the stomach can occur with high risk of necrosis and perforation. An upper GI contrast study or even a plain abdominal X-ray is diagnostic (Figure 1D). Immediate deflation of the band followed by emergency laparoscopy is needed. At laparoscopy the band can be opened and the stomach, when ischemic but not necrotic, can be left in place for a re-laparoscopy and repositioning of the band several days later. Alternatively the band can be removed and the patient planned for elective conversion to another procedure.

CONCLUSION

There is a distinct group of patients that can effectively be treated with an adjustable silicone gastric band, which remains a safe and effective operation. However, as there is not one single surgical procedure that will be permanently effective in any patient, revisions and conversions will be required.

Patients who had a good result with the SAGB but who have either a mechanical failure or a secondary pouch problem can be treated effectively by surgical correction. It is also shown that when a band fails conversion to another technique is safe and effective. It is obvious that revisions and conversions need to be done in centers of excellence and by experienced surgeons as these procedures can be complex and do carry a slightly higher risk.

ABSTRACT

In the last 15 years, LSG has become increasingly popular as a primary procedure because of its simplicity, relative safety, and effectiveness to achieve sustained weight loss over time. LSG has demonstrated its effectiveness in achieving weight loss and resolution of obesity related co-morbidities. Despite good success rates, it may occasionally be associated with failure. LSG failure is defined by insufficient weight loss, weight regain, surgical complications, and poor control of comorbidities such as gastro-esophageal reflux disease (GERD). As demand for LSG increases, so will the need for revisional surgeries. The incidence of revision varies according to the studies analyzed but revision rate following primary LSG is reported to be between 5-30%. Revisional surgery is technically more demanding, and associated with higher complications and mortalities compared to primary bariatric procedures. Complication rates between 0 and 46% have been reported after these reoperations. In this chapter, we will analyze the potential causes of LSG failure as well as the suggested revision surgeries.

1. INTRODUCTION

Sleeve Gastrectomy was first created by Hess and Marceau in 1998 as the first part of the duodenal switch (DS) operation [1, 2]. In high risk and super-super obese patients, the gastric sleeve part of the DS operation was often performed alone in an attempt to reduce morbidity and mortality, and to facilitate the laparoscopic approach [3].

Owing to the relative technical ease, low complications rates and good weight loss results, it was found that laparoscopic sleeve gastrectomy (LSG) could be performed in many cases as a stand-alone bariatric operation [4]. Technical details of LSG vary, but the ultimate goal of the procedure is to remove the vast majority of the stomach, especially the fundus, leaving only a thin gastric tube from the esophagus to the duodenum. The absence of gastrointestinal anastomosis during the operation, and leaving patients with an intact gastrointestinal (GI) tract are other potential benefits of this relatively new technique.

In the last 15 years, LSG has become increasingly popular as a primary procedure because of its simplicity, relative safety, and effectiveness to achieve sustained weight loss over time. A recent meta-analysis data by Buchwald and colleagues suggests LSG is the second leading bariatric operation in the world, only surpassed by laparoscopic Roux-en-Y gastric bypass (LRYGB) [5]. As demand for LSG increases, so will the need for revisional surgeries. In this chapter, we will analyze the potential causes of LSG failure as well as the suggested revision surgeries.

2. LAPAROSCOPIC SLEEVE GASTRECTOMY (LSG) FAILURE

LSG has demonstrated its effectiveness in achieving weight loss and resolution of obesity related co-morbidities [6]. Despite good success rates, it may occasionally be associated with failure. LSG failure is defined by insufficient weight loss, weight regain, surgical complications, and poor control of comorbidities such as gastro-esophageal reflux disease (GERD) [7, 8]. LSG patients appear to be subjected to weight regain after more than 3 years. Himpens et al., noted that more than 30% of the LSG patients had inadequate weight loss or weight regain, requiring an additional procedure [9]. This is similar to what has been reported with other restrictive weight loss operations such as the adjustable gastric band (AGB), or the vertical banded gastroplasty (VBG) [10, 11]. Several factors may be responsible for late weight regain after sleeve gastrectomy. These factors include dietary factors, and changing eating habits to high caloric meals. Long term anatomic changes with the sleeved stomach dilatation might allow the patient to consume larger amounts of food, thus contributing to weight regain as well [12]. Furthermore, loss of patient follow-up and counseling, may also play an important role in weight regain. Surgical complications after LSG can lead to procedural failure [8]. A recent systematic review of the literature on LSG including a total of 15 studies (n = 940 patients) revealed overall complication rates of 12.1%. Reported complications include bleeding or leakage from the staple line, strictures, delayed gastric emptying, gastric dilation, and vomiting [13]. LSG failure is however multifactorial and finds a feeding ground in patient's poor adherence, procedure failure, and surgeon error.

3. REVISIONAL SURGERY AFTER LSG FAILURE

The prevalence of revisional surgery increases as the number of LSG procedures rises. The incidence of revision varies according to the studies analyzed but revision rate following primary LSG is reported to be between 5% and 30% [9].

Revisional surgery is technically more demanding, and associated with higher complications and mortality compared to primary bariatric procedures. Complication rates between 0 and 46% have been reported after these procedures [7]. Revision of previous bariatric operations carries a higher overall risk of leakage. A review of revisional bariatric surgeries conducted by Jones et al., (n = 838 patients) reported a 14% (n = 118) major complication rate and 0.8% (n = 7) mortality rate. The study also noted that complication rates were lower in the laparoscopic patients with no mortalities in this group [14]. This challenging scenario obligates bariatric surgeons to have solid options in revisional surgery after LSG failure [15-19]. Revisions are technically demanding due to the increased tissue fibrosis and the altered anatomy following the primary procedure [20]. The currently accepted alternatives for the patients who require revisional surgery for failed LSG are detailed as follows.

3.1. Laparoscopic Re-Sleeve Gastrectomy (LRSG)

Laparoscopic re-sleeve gastrectomy (LRSG) was initially reported in 2003 as revision for poor weight loss after DS [21]. Since its first description by Gagner et al., several case series have been published [13]. Baltasar et al., showed feasibility of LRSG in the super-super obese patients, when the resulting gastric pouch is too large or dilated after the original LSG [12]. Another retrospective study included 13 patients with ineffective weight loss (%EWL < 50%) or weight regain who underwent LRSG. All patients underwent a preoperative upper GI series showing persistent fundus at the time of revision. Weighted mean preoperative body mass index (BMI) and excess weight were 44.6 kg/m² and 61.8 kg, respectively. After 12 months follow-up, mean BMI, percent of EWL, and percent of BMI loss decreased to 27.5 kg/m², 71.4%, and 82.8%, respectively. There was no morbidity reported [16]. However, LRSG results are far from being complications free, and complications at time may be severe in nature [22]. Within a smaller case series study (n = 7) of patients undergoing LRSG Dapri et al., reported one leak at the angle of His, and less successful weight loss than for primary cases [15]. Interestingly, Rebibo et al., retrospectively evaluated outcomes in 15 patients having LRSG after failure of LSG [18]. These patients were matched (age, gender, BMI, and co-morbidities) 1:2 with patients undergoing first line LSG. The mean operating time was longer in the LRSG (116 vs. 86 min; $p \leq 0.01$), and postoperative complications were higher in the re-sleeved patients. Two patients experienced leakage and one died. At 12 months the EWL was 66% for the LRSG and 77% for the primary LSG group ($p = 0.05$) [18].

The results of the above mentioned studies suggest that LRSG can achieve significant short-term weight loss at 24 months follow-up but at the cost of substantial peri-operative complications.

3.2. Laparoscopic Gastric Bypass (LRYGBP) or Omega Loop Mini Gastric Bypass (LMGB)

The conversion of a failed LSG to laparoscopic gastric bypass (LGB), considered by many the “gold standard” bariatric procedure, has been accepted as a revisional option because of the reasonable balance between weight loss and complications.

A recently published systematic review of revisional surgery following failed primary LSG reported weight loss improvement in more than 100 patients (6 studies) with laparoscopic gastric bypass (LGB) (laparoscopic Roux en Y gastric bypass (LRYGB) or omega loop mini gastric bypass (LMGB)) as a revisional procedure [23]. Mean preoperative BMI was 41.9 kg/m², which decreased after conversion to 38.9 kg/m² at 3 months, 36.5 kg/m² at 6 months, 33.7 kg/m² at 12 months, and 35.7 kg/m² at 24 or more months of follow-up. Percentage of EWL was 48% over the last follow-up period (i.e., 24 months). Similar trends in weight loss results have been recently published with 21 patients undergoing LMGB; a single gastro-jejunal bypass anastomosis connecting the gastric sleeve to a jejunal loop (200 cm downstream from the ligament of Treitz). Mean BMI at 12 and 24 months after LMGB was 34.6 kg/m² and 35.7 kg/m², respectively [24].

The Fourth International Consensus Summit on Sleeve Gastrectomy [25], a recent survey of 88 bariatric surgeons experienced in LSG (average of 295 operations per surgeon), reported that LRYGB was the preferred option if a second operation is required for weight regain after LSG [25]. Twenty % consider LRSG, 46% conversion to LRYGB and 24% conversion to BPDDS.

However, strong evidence suggests weight loss outcomes after LGB are similar to those after LRSG. Cheung et al., [23], reported short-term weight loss outcomes after failed LSG. At 24 months, mean BMI and percentage EWL were 35.7 kg/m² and 48%, for the LGB group (n = 114) vs. 35.3 kg/m² and 44%, for the LRSG group (n = 45). The article review concludes there are no significant differences in weight loss improvement between both procedures. Langer et al., reported satisfactory results of 8 patients converted to LGB because of insufficient weight loss and severe reflux disease [17]. Interestingly, the authors emphasized that patients undergoing conversion to LGB after LSG could be more prone to regain weight.

Perioperative complications after LGB as revisional procedure have also been reported. Moszkowicz et al., described a morbidity rate of 9.5% after LMGB [24]. A prospective case series study from the Netherlands (n = 18 patients) reported successful results within the LGB as a revision procedure in terms of weight loss, GERD, and dysphagia [19].

However, associated peri-operative complications were significantly high and included anastomotic leakage (n = 2), intra-abdominal bleeding (n = 2), splenectomy, wound infection, and cardiac decompensation.

LSG has been reported to carry a risk of GERD. A retrospective study (n = 30) evaluated long term side effects after LSG. More than 20% of patients in the study reported severe GERD or vomiting at 6 years after the procedure [9]. Weiner et al., reports a 15% incidence of GERD in a cohort of 76 subjects, which was improved by conversion to LGB [26].

In this clinical situation, conversion to LGB is a consistent option for management of GERD related complications after LSG (Figures 1-4).

3.3. Laparoscopic Biliopancreatic Diversion with Duodenal Switch (BPDDS)

Sleeve gastrectomy was primarily planned as the first stage of a two stage duodenal switch, hence making the BPDDS a logical candidate for revisional surgery after SG. However, patients who underwent LSG, as a premeditated and planned strategy for eventually performing BPDDS should not be considered as benefiting from a “true revisional procedure” for failure and are not analyzed in this chapter.

Figure 1. Conversion from LSG to LGB.

Figure 2. Conversion from LSG to LGB; gastric sleeve dissection.

LSG conversion to BPDDS has some potential advantages. There is no need to dissect and manipulate the stomach, which may ultimately decrease gastric leak rates, and other peri-operative complications compared to those observed in a primary BPDDS procedure.

Single-stage BPDDS has been reported to have higher complications rates [27]. Iannelli et al., retrospectively compared 110 super-obese patients ($\text{BMI} \geq 50 \text{ kg/m}^2$) undergoing the two staged DS with 110 patients (matched for age, gender and BMI) undergoing the single-stage DS [28]. The postoperative complication rate was 8.2% in the staged approach and 15.5% in the single-stage DS group. Multivariate analysis showed that single-stage DS was the only predictive factor of complications (odds ratio 2.36; 95% confidence interval 1.001-5.61) [28]. A small study evaluated outcomes in 9 patients with failed LSG converted to DS [15].

Figure 3. Conversion from LSG to LGB; gastric pouch transaction.

Figure 4. Conversion from LSG to LGB; gastrojejunal anastomosis.

There were no conversions in the study but operative time was considerably long (mean 152.6 ± 54.3 minutes). Complications included one patient with bleeding, one patient with a duodenoileostomy leak, and one with a duodenoileostomy stenosis. Weight loss at 25 months follow-up was successful; mean 25 month BMI and percent EWL was 27.3 ± 5.2 kg/m² and $73.7 \pm 27.7\%$. During follow-up, 2 patients required revision due to hypoproteinemia and diarrhea (feeding jejunostomy tube) [15].

Thus, BPDDS as revisional surgery after LSG failure, promotes substantial weight loss improvement but at the cost of relatively high complication rates.

3.4. Miscellanea of Revisional Procedures

After failed sleeve gastrectomy, some alternative procedures have been described in an attempt to minimize surgical complications and improve weight loss outcomes.

Among these, single anastomosis duodenoileal bypass [29], plication of the sleeve [30], banded sleeve [31], butterfly gastropasty (micro funnel shaped pouch) [32], and side to side jejunoileal anastomosis, are the most important.

Results however continue to remain limited to case reports, and very small case series, hence no conclusions can be drawn.

Figure 5. Proposed algorithm of treatment after LSG failure.

Table 1. Failed Primary Laparoscopic Sleeve Gastrectomy Studies

Author	Year of publication	Type of study	n (size)	Age (years)	Pre-op BMI (kg/m ²)	Revisional Procedure

CONCLUSION

In general, revisional surgery is technically more demanding than primary bariatric procedures, and must be performed with extreme care. Such operations should be carried out in tertiary centers with experienced bariatric surgery programs that can limit the incidence and severity of peri-operative complications.

Furthermore, the selected type of revisional procedure should take three different considerations into account: the individual patient history and cause of failure, the difficulty of the revisional procedure, and the bariatric surgeon's experience.

After thorough revision of the available literature, it appears that revisional surgery for LSG failure overall offers weight loss improvement at 24 months. In summary: while LRSG, and LGB appear to be reasonable options with well-adjusted results and complication rates, the conversion to a BPDDS appears to create an increased weight loss but at the cost of major morbidity. LGB can effectively manage intractable GERD after LSG. Unfortunately, the data in revisional sleeve gastrectomy is limited, and long term randomized controlled studies are required to compare weight loss outcomes and complication rates.

ABSTRACT

The Roux-en-Y gastric bypass procedure is considered by many the “state of the art” bariatric intervention. Nevertheless, as any other weight loss/ metabolic operation it requires a strict follow up and good patient compliance to avoid the development of poor dietary habits. The most dreaded dietary flaw is without doubt sweets eating, which constitutes the ruin for all bariatric procedures. Poor weight loss outcomes may however be the consequence of anatomical aberrations of the bypass construction as well. In addition, surgical complications may arise all along the postoperative course of the bypass patients. Complications and anatomical flaws may warrant surgical intervention to correct the anatomy, or, in some occasions, to radicalize the bypass or to convert the bypass to another type of bariatric/metabolic procedure.

The decision to surgically re-intervene must be backed up by the conclusions of a multidisciplinary consultation.

INTRODUCTION

The Roux-en-Y gastric bypass (RYGB) is considered the gold standard for bariatric (“metabolic”) surgery. The procedure existed long before the laparoscopic infatuation and survived the rise of several upcoming fashionable operations such as the adjustable band (AGB) and the previously abandoned vertical banded gastroplasty (VBG) (the latter witnessed a revival because of the laparoscopic approach [1])

RYGB has undergone a substantial evolution over the years, both with the open, “classic” or the minimally invasive approach. In its initial embodiment RYGB as proposed by Mason [2] involved the creation of a horizontal stomach pouch, which, consequently, comprised a significant portion of the stomach fundus. With time, it became clear that the construction with horizontal stomach pouch was quite sensitive to dilation and subsequent failure. Newer versions of the RYGB, involving the use of the lesser curvature part of the cardia for pouch creation were popularized by surgeons such as Griffen [3]. With the advent of laparoscopy the technically quite complex RYGB procedure experienced a drop in popularity to the benefit of LAGB. In 1994 however Allan Wittgrove [4] and colleagues succeeded in performing a full- laparoscopic RYGB (LRYGB). Nevertheless, it took several years before the laparoscopic procedure benefited from general acceptance by the surgical community. Recently, the laparoscopic version of RYGB regained the pole position in terms of most popular and most performed bariatric operation [5]. Presently LRYGB is usually performed according to a few technical variations. Whereas initially the alimentary limb (AL) (Figure 1) was constructed some 150 cm long and the biliopancreatic limb (BPL) was kept rather short (which would allow endoscopic access to the excluded duodenum, stomach and biliary tree), more recently there is a tendency to reduce the length of the AL and to lengthen the BPL [6].

This new modification allegedly increases weight loss and enhances the metabolic impact of the construction.

In terms of anastomotic technique in RYGB, some surgeons prefer the handsewn technique [7], in contrast with others who choose the circular stapled technique [8] or the linear stapled technique [9]. Most surgeons by now close the potential hernia defects (Figure 2), but others claim that closure is not necessary [10]

Despite the popularity of LRYGB, many surgical teams recently made the switch to supposedly simpler procedures including the sleeve gastrectomy (LSG) and the mini gastric bypass (MGB), often called the omega loop or single anastomosis gastric bypass (OLGB, respectively SAGB). Of note, the “newer” procedures have not yet sustained the test of time and little is known about the long-term outcomes.

Over the years it has been shown that follow-up is crucial for a successful gastric bypass. Adequate follow-up with periodical blood analysis is necessary, not only to dietary flaws (especially the abuse of carbohydrates and simple sugars), but also to detect the development of vitamin, mineral and protein deficiencies [11].

As all bariatric procedures LRYGB has some drawbacks. Even with good follow-up, problems may occur that need correction. Consequently, considering the high number of patients who have undergone LRYGB, it is inevitable that some individuals will need correction of the bypass construction for different reasons. It is the aim of this chapter first to analyze possible complications or unwanted side effects (such as insufficient weight loss and

weight regain) that will need correction, and, second, to provide solutions to address this issue.

Figure 1. The typical “old fashioned” Roux-en-Y gastric bypass with relatively short biliopancreatic limb (BPL). The small gastric pouch (GP) is anastomosed to the alimentary limb (AL) that lies anterior to the stomach remnant (REM) and the colon. The junction of AL and BPL results in the common limb (CL).

Figure 2. The 2 most important defects created by the Roux construction: Petersen's defect (P) between the mesentery of the alimentary limb (AL) and the transverse mesocolon and the mesenteric gap situated between the mesenteries of the biliopancreatic (BPL) and the common limb (CL).

1. Types of Failures

Failures of gastric bypass can be divided into several categories:

- Some patients never reach sufficient weight loss, which may be due to anatomical reasons or to lack of discipline of the patient (poor diet habits, failure to adhere to the follow-up program). These failures are considered *primary failures*.
- Some patients initially did experience successful weight loss but subsequently suffered weight regain. This evolution may be due to anatomical reasons (such as pouch dilation or gastrogastic fistula), but is most often caused by changed dietary habits of the patient. These failures are called *secondary failures*.
- Some patients suffer a *complication* that demands surgical correction. Examples of complication are intractable gastro-esophageal reflux (GERD), with or without hiatal hernia (HH), herniation of the gastric remnant through the hiatus, food intolerance because of long-term anastomotic stenotic problems, ulceration of the anastomosis, ulceration in the gastric remnant, blind loop symptoms at the level of the gastro-enteral or the entero-enteral (jejunojejunal or JJ) anastomosis, internal herniation with obstruction of the AL, the BPL or the common limb (CL), intussusception at the level of the alimentary-biliopancreatic confluent, trocar incision herniation, and problems concerning glucose metabolism, such as neuroglycopenia.

2. General Considerations in Revision or Conversion

As in every bariatric-metabolic procedure it is essential to analyze the cause of failure of LRYGB,. Analysis must involve thorough evaluation of the anatomical integrity of the bypass construction. Anatomical alterations often may remain silent and not interfere with the clinical outcome. In face of poor clinical results, however, anatomical alterations should be addressed. Alterations may be situated in any of the components (i.e., the gastric pouch, shape or volume, the diaphragmatic hiatus, the length of the limbs). In some occasions the aberrant anatomy may be deemed too complicated and conversion to a different type of procedure (e.g. conversion to a distal RYGB) while keeping the gastric pouch and anastomosis as they are may be preferred. The most radical conversion procedure consists of reversal but should only be considered under rare circumstances.

Simple reversal will most likely result in weight regain and resurgence of co-morbidities. Consequently, reversal procedures will most often be combined with conversion to a restrictive construction such as SG.

Whenever a substantial change in anatomical construction is anticipated, a multidisciplinary team should be consulted to address all the aspects of the required therapeutic change. In our practice, the multidisciplinary team consists of a dietitian, a psychologist, a gastroenterologist, an endocrinologist, and, last but not least, the bariatric surgeon. Multidisciplinary evaluation is organized by the *bariatric coordinating nurse*, who because she personally knows the patients can best evaluate the capacity of the patient to deal with newly induced dietary restrictions, lifestyle changes, compliance with supplementation and medication and acceptance of a proposed new operation. The *psychologist's* task is to

evaluate how the patient has progressed since the preoperative assessment. In some instances the patient will demonstrate a psychological incapacity or refusal to deal with the characteristics of the bypass. In contrast, sometimes the patient may have developed unrealistic expectations and must be taught to accept the actual outcome of the LRYGB in terms of weight loss, even when the outcome does not match his/her expectations. The patient must also be educated about the impact of a new surgical procedure that may, for example, significantly impair the capacity of ingesting food. This impairment may in some occasions surpass the psychological capacities of the individual. The *dietitian* analyzes the patient's dietary response to the bypass itself. When restriction is still active, some patients overcome the imposed small size of meals by increasing the frequency of meals (polyphagia). When restriction has weaned off, patients often experience the tendency to increase the size of their meals (hyperphagia) [12]. Alternatively, some subjects no longer observe the strict dietary restrictions such as the abstinence from sugars that were imposed at the time of surgery. Typically, some patients will preferably choose carbohydrates, especially liquid ones, because they no longer experience any dumping sensation - the alleged primary deterrent from ingesting sweets [13]. Typically, sweets eating will not warrant a surgical solution, because, as demonstrated by Scopinaro, this evolution is resistant to all bariatric constructions [14]. Consequently, the dietitian's main task consists of putting the patient back on the "right track".

The *gastroenterologist* and the *radiologist* evaluate the shape and volume of the different bypass components and will in addition check for possible significant changes such as marginal ulcers, HH, or gastrogastic fistula. Besides confirming the diagnosis made by the radiologist, the endoscopist may attempt to correct some of the detected anatomical aberrations and proceed to reducing the size of the pouch or trying to close a gastrogastic fistula. Interventional endoscopy has recently gained an important position in the correction of bypass failures but because of the novelty of the technique and lack of mid- to long-term outcome reports this aspect will not be further addressed in the present chapter.

The *endocrinologist* investigates the possible insufficient improvement or resurgence of comorbidities, and, depending on the severity of the findings, may orient towards a surgical solution to address this issue. Conditions amenable to improvement with operative treatment include dyslipidemia, arterial hypertension (AHT) and type 2 diabetes (T2DM). When the aforementioned diseases have not substantially improved, or have re-emerged after initial remission or improvement either the patient's dietary compliance or the team's choice for the bypass procedure itself may be questioned.

The *bariatric surgeon* must evaluate the safety of an anticipated re-intervention, taking the specific history of the patient into account. Patients who postoperatively suffered a leak at the gastro-enterostomy for instance may not be ideal candidates for undergoing procedures involving the pouch part of the RYGB construction. Depending on the indication, the surgeon may decide to opt for a procedure that will influence the length of the limbs rather than to alter the volume of the pouch.

The final decision for any bariatric reintervention should always be based on evaluation of all results by the *multidisciplinary team*.

3. Primary Failure

Primary failures are rare after RYGB. Except for the cases where the patient displays an outrageous lack of dietary discipline, primary failures should always raise the suspicion of anatomical causes. In primary failures the most obvious culprit for poor weight loss is a poorly designed gastric pouch, that may have been constructed too large, or that has been made of parts of the stomach that are too distensible. Several strategies have been described to address this issue.

3.1. Reshaping the Pouch

A poorly constructed gastric pouch (i.e., too large a pouch, or a pouch including the fundus) may be found, usually in patients who previously underwent another bariatric procedure such as LAGB or LSG, and in whom poor dissection of the apical part of the stomach results in the keeping of a large pouch, usually located posteriorly. Another possible anatomical cause for poor weight loss is the presence of a gastrogastic fistula, a condition that results in the abolition of the bypass physiology. The gastrogastic fistula may sometimes be the result of an imperfect transection of the stomach, usually located at the uppermost part of the staple line [15], but is most often caused by a perforating marginal ulcer, that connects the staple line of the anastomosis with the horizontal staple line on the remnant stomach [16]. Diagnosis and treatment strategy are based on a multidisciplinary approach. It is however noteworthy that in some occasions a gastrogastic fistula will only be discovered at surgical re-exploration. Correction of too large a pouch consists of extensive dissection of the gastric pouch, but only on the left sided part of the latter to avoid ischemic problems, because the blood supply essentially is provided by the vessels at the lesser curvature side of the stomach pouch. Usually the anastomosis itself can be kept as is. After complete dissection of the gastric pouch a re-resection can be performed under safe conditions, guided by a large bore gastric tube introduced by the anesthesiologist and kept in close contact with the lesser curvature of the stomach pouch. The resection of the pouch is best performed with a linear stapler with green or black load because the tissues invariably will be thickened. Alternatively, the fully dissected lateral aspect of the gastric pouch can be imbricated (or plicated), which has the advantage of being cheaper and possibly reduces the risk of fistula caused by staple line dehiscence. During reshaping of the pouch we usually perform dissection and resection of the fundic part of the remnant as well, in an effort to rule out all possible hidden gastrogastic fistula [17]. Typically, resection of the remnant will be carried out from the top down to the level of the antrum, i.e., to the right of the alimentary limb, because as mentioned above, a gastrogastic fistula of the posterior aspect of the gastro-enteral anastomosis (GEA) is always possible. Dissection of the part of the remnant lying across the anastomosis is obscured by the mesentery of the alimentary limb and must be performed, at the risk of devascularizing that part of the remnant, which is another reason why we do not hesitate to perform resection of its fundic part.

3.2. Banding the Pouch

RYGB is commonly seen as a mixed procedure (mixed restrictive and malabsorptive). Even with a correctly constructed pouch and gastro-enterostomy (GEA) the restrictive aspect may not suffice in some instances and may find benefit from additional measures. These

measures include the placement of a non-adjustable band around the bypass pouch as reported by Fobi in open RYGB [18], and more recently by Bessler in laparoscopic procedures [19]). In our [20] (and in others') experience the secondary placement of a band is however fraught with a high erosion rate (in our experience up to 20%). Another, perhaps better option for addressing poor weight loss after RYGB consists of the placement of an adjustable band (AGB) around the gastric pouch as described by Bessler [21].

After banding the pouch with an AGB, further weight loss, varying from 55.9%–94.2% excess body mass index loss (EBMIL) has been documented after respectively 12–42 months of follow-up [22]. While theoretically the incidence of erosion after placement of an adjustable band should be lower than with a non-adjustable (Fobi) ring, adjustable band-specific complications such as slippage, infection and erosion of the band may appear. In case of one of the aforementioned mishaps it is better to remove the band (=foreign object), if at all possible by endoscopic technique, and to trim the pouch over a large bore tube.

3.3. Longitudinal Partial Resection of Pouch and Alimentary Limb (Gagner Technique)

Michel Gagner's team developed an interesting technique to influence the volumes involved in the bypass in an effort to resume weight loss without using a foreign object [23]. The technique consisted of reducing the gastric pouch together with the proximal part of the antimesenteric edge of the AL with a linear stapler. Long-term weight loss outcomes of this ingenious technique were however disappointing, both in Gagner's and in our experience. Rather than resecting the pouch and the AL longitudinally, we also attempted to reduce both by plication around a 34 Fr orogastric tube, quite similarly to the newly described technique that mimicks SG [24]. Unfortunately, here as well, midterm outcomes concerning weight loss were rather poor.

3.4. Endoscopic Trimming of Pouch and Gastro-Enteral Anastomosis

Recently, several techniques have been described to reduce the size and/or the compliance of the gastric pouch and to reduce the size of the GEA. As previously mentioned, these techniques are beyond the scope of this chapter.

3.5. Reversal and Conversion to Sleeve Gastrectomy

When all possible correctible causes for primary failure of the RYGB have been ruled out the multidisciplinary team may conclude that the choice for RYGB was not the correct one and may decide to reverse the bypass. See below (4.2).

4. Secondary Failure

Secondary failure occurs when patients who initially experienced good weight loss and resolution of co-morbidities suffer a significant weight regain and resurgence of the comorbidities. This evolution indicates that the procedure most likely was indeed correctly chosen and well carried out (as demonstrated by the initial success), but that some unwanted evolution did interfere with continued weight loss. Causes of weight regain may well be patient related (diet, life style) or may be linked with anatomical changes that have developed

over the years. There are conflicting data in the literature concerning the importance of the secondary dilation of the pouch, and of the dilation of the GEA [25, 26]. Based on the (poor) experience gathered with pouch trimming and anastomotic reshaping performed for primary failure, we cannot recommend a surgical re-intervention that limits itself to these objectives. In secondary failures the pouch can be banded (by adjustable or non-adjustable band) as well, but, as mentioned before, this strategy does carry its own complications. In addition, patients who got used to the quite comfortable eating conditions secondary to the RYGB more often than not will only reluctantly accept a new significant reduction.

4.1. Distalization of RY Gastric Bypass

The RYGB being a mixed restrictive-malabsorptive procedure, the malabsorption may be enhanced as well. Malabsorption can be augmented by increasing the length of the bypassed bowel. Consequently, the conventional “proximal” bypass may be converted into a “distal bypass”. Because of the substantial number of severe complications described in the literature, distalization of the bypass is only performed in well-compliant individuals who nevertheless developed weight regain after initial good weight loss. The best candidates are the patients who did not dilate their gastric pouch (hence cannot eat large volumes), but who developed a grazing (or polyphagic) eating pattern.

Lengthening the AL to 200 or even 250 cm has proven useless on the long term for patients who failed the RYGB [27]. Conversely, “true” distal gastric bypass has been proposed several years ago as active remedial operation for failed RYGB. While extremely effective in terms of weight loss, the side effects of the distal construction however have proven too significant to allow general acceptance of the procedure. In the initial description by Sugerman, who used the distalization principle in patients who did poorly after (open) proximal bypass, the metabolic consequences were considerable and some patients died [28]. Brolin [29] found that only half of the patients had clear benefits from the conversion of a regular to a distal RYGB. However, Brolin described a particular type of distal bypass, with a very long alimentary channel and a very short (75 cm) common channel. Our technique of bypass distalization much more resembles the open operation described by Rawlins et al. [30], who reported good results in compliant patients with a construction of a 100 cm long CL and a 150 cm AL. We actually maintain a length of 150 cm both for the AL and the CL, the BPL not being routinely measured [31].

This technique has the practical advantage that mostly the alimentary limb had been constructed some 150 cm long, hence that all that needs to be done is to transect the alimentary flush with the entero-enteral anastomosis and to reimplant the alimentary limb on the common some 150 cm proximal to the ileocecal valve. Thus, the sum of AL + CL is approximately 300 cm, the minimum length to avoid protein malnutrition according to Scopinaro [14]. With our distalization strategy, besides inducing good additional weight loss in a good number of individuals, we managed to “cure” a patient from insulinodependent T2DM, despite a weight loss of approximately 50% EBMIL obtained by the “regular” RYGB. It is clear however that after distalization patients become at high risk to develop deficiencies including protein malnutrition, hence the obligation to select the patients in terms of compliance (as demonstrated by their behavior after the initial RYGB) and the commitment of both patient and multidisciplinary team to zealously follow-up the patient at regular intervals.

4.2. Reversal (Figure 3-11) and Conversion to Sleeve Gastrectomy (as First Step of a Duodenal Switch or DS)

For some individuals the RYGB induces dietary restrictions -such as the interdiction of ingesting sugar- that proved too hard to keep. Non-compliance to the diet however results in an array of undesired symptoms including hypoglycemia and eventually weight regain.

For these patients, the RYGB appears to represent a “wrong choice” on the long-term and it might consequently be better to change the metabolic-surgical strategy overall. Converting one procedure to another or even simple reversal of a procedure nowadays is less of a challenge than in the open surgery era, because laparoscopy causes far less adhesions. In order to allow more than one final choice it is an acceptable policy to initially reconvert the bypass anatomy to a normal situation. We described the technique in 2006 [32] and reported on our patients’ outcomes a few years later [33].

Figure 3. The gastro-ental anastomosis must be taken down, uniting the gastric pouch (A) and the proximal part of the alimentary limb (AL). The gastro-ental anastomosis is being transected (separation of A and B). Transection is performed just distal to the anastomosis to create ischemic discoloration of the most proximal part of the AL, which facilitates identification of the gastric pouch part at the anastomosis. Thanks to the ischemic discoloration of the most proximal part of the transected AL the trimming-of the gastric pouch can be kept minimal.

Obviously, reconversion to a normal anatomy will not likely improve weight loss. However, starting from the newly re-obtained normal anatomy, a LSG can be constructed, either immediately during the reversal or with some delay to give the patient the occasion to accommodate to the new situation [34]. A “sleeve-like” gastrectomy can be performed over a 34-French bougie to calibrate the new stomach. (Figure 10), while imbricating (“plicating”) the middle part of the sleeve proximal to the antrum of the stomach. (Figure 11).

It appears that in some cases LSG is actually superior to RYGB, possibly because of the preservation of the antrum and pyloric sphincter, with subsequent enhanced gastric emptying [35] and inhibition of the orexogenic Ghrelin hormone [36]. In addition, in cases in which the restriction created by the sleeve does not suffice, the “natural complement” of the LSG, i.e., a DS may be carried out. DS is a typical biliopancreatic diversion, and has been shown to be the most active procedure in terms of T2DM remission rates [37]. In addition, because of the preservation of an acceptable stomach volume (i.e., the sleeved stomach), unlike with the distal gastric bypass, the DS might be safer than the distal RYGB.

Figure 4. A gastrotomy is performed in the remnant vis-à-vis the distal part of the pouch, that is opened in its distal part at this time.

Figure 5. Anastomosis is performed between the open pouch and the remnant (Posterior layer). A manual anastomosis is preferred. Please note that the vertical part of the pouch and the corresponding part of the remnant are not opened, but rather sutured together to restore a fundus-like structure to avoid reflux.

Figure 6. Anastomosis is performed between the open pouch and the remnant (Anterior layer). A manual anastomosis is preferred. Please note that the vertical part of the pouch and the corresponding part of the remnant are not opened, but rather sutured together to restore a true fundus to avoid reflux.

Figure 7. The JJ anastomosis is being transected at C, separating the BPL from the AL-CL confluent. Note that first the original mesenteric defect must be recreated and that the linear stapler is placed slightly on the BPL side of the anastomosis to avoid narrowing at the AL-CL junction. A rim of ischemic tissue may thus be left on the AL-CL side of the anastomosis, but this has no clinical significance.

Figure 8 and 9. Anastomosis between B (previously the proximal AL) and C (previously the BPL), restoring the continuity of the small bowel. Care must be taken not to twist the mesenteries of the 2 small bowel loops. With the technique usually chosen for RYGB the mesenteric defect at this anastomosis should be quite small.

Figure 10. A “sleeve-like” gastrectomy can be performed by the use of a 34-French bougie to calibrate the new stomach. The technique starts by devascularizing and resecting the fundus, ending a few cm proximal to the level of the newly fashioned anastomosis.

Figure 11. Plication of the middle part of the sleeve proximal to the antrum of the stomach.

5. Revisional Procedures after RYGB for Complications Interfering with the Outcome

5.1. Hiatal Hernia and Gastro-Esophageal Reflux (GERD)

Despite the recognized efficacy of the RYGB anatomy in abolishing GERD, reflux symptoms may complicate even RYGB. Usually, reflux will be alkaline, but acid reflux is possible as well, perhaps as a result of too large a gastric pouch or too a short an AL, or, more frequently, as a result of an abnormal communication between the bypassed gut and the pouch or the AL as seen in gastrogastic fistula. Alternatively, an obstruction may be causing acid reflux, as in cases with severe adhesions impacting on the CL or in trocar orifice herniation.

In case of alkaline reflux, a Hiatal Hernia (HH) must be ruled out.

HH can be highly symptomatic after RYGB, not only in terms of GERD, but in terms of dysphagia as well. The latter condition may induce excessive weight loss, which may warrant reintervention. Rarely, HH involves herniation of the excluded stomach, a situation that requires immediate reoperation because of the risk of strangulation.

Figure 12. Our personal technique of crural repair. While the fully dissected distal esophagus (ESO) is reclined anteriorly, the posterior closure of the hiatal crura is performed by at least one figure of 8 stitch of polypropylene material buttressed by cellulose acetate pledgets.

When performing hiatal exploration a thorough circular exploration of the crura must be performed as well as dissection/liberation of the distal esophagus, the latter being important to rule out epiphrenic diverticula and to provide sufficient slack for the intra-abdominal esophagus, an essential condition in avoiding recurrence [38]. In our experience, crural repair is best performed by posterior placement of non-absorbable, deep stitches, that are then tied over pledgets (we usually use cellulose acetate pledgets) [39] (Figure 12). The use of prosthetic mesh is best avoided because of the risk of erosion in a previously dissected area.

5.2. Issues at the Gastro-Enteral Anastomosis

A dreaded problem at the GEA is the anastomotic or marginal ulcer, a condition that occurs in up to 50 % of the cases [40]. Causative factors include excessive acid production as with a large pouch (but again, a gastrogastic fistula must be ruled out), ischemia, and the persistence of foreign material (staples or non-absorbable sutures). Marginal ulceration appears more frequently in smokers. When conservative management including the use of large doses of proton pump inhibitors (PPI) fails, surgical treatment may be considered. In case of perforation, surgical treatment must be performed immediately.

5.2.1. Elective Treatment of Marginal Ulceration

The first treatment of chronic marginal ulcer is the cessation of cigarette smoking. Smoking is a leading cause of recurrent anastomotic ulceration.

Surgical exploration should aim at reducing the acid production, e.g. by reducing the size of the pouch, by performing vagotomy, or, more radically, by performing remnant gastrectomy to permanently reduce gastrin and subsequent acid production. Even in the presence of small pouches, in case of chronic marginal ulcer, we usually resect the GEA together with a chunk of pouch, care being taken not to induce ischemia.

To avoid vascularity issues, dissection at the lesser curve is kept minimal and transection (either stapled or preferably manual, with the coagulating hook) performed at an angle, keeping the greater curvature part of the pouch substantially shorter than the lesser curvature. Reanastomosis is preferably performed manually to avoid ulcer-inducing staples. We usually perform resection of the fundus as well, with the purpose to allow better visualization of the greater curvature side of the pouch, and to reduce systemic acid production overall.

5.2.2. Emergency Treatment of Marginal Ulceration

When faced with perforated anastomotic ulceration, the surgical treatment should be confined to dealing with the acute situation, i.e., the perforation itself. Trimming of the edges of the ulcer and suture closure covered by an omental patch is probably the best initial treatment. Because of the invariably present concomitant peritonitis, it is preferable to delay more extensive treatment such as described in 5.2.1. (the search for a gastro-gastric fistula, trimming of the pouch and total reconstruction of the GEA) to a later date, when septic symptoms and acute inflammatory changes have subsided.

In exceptional cases the perforation involves the remnant part and a bulbar ulcer may be found. Treatment should be as for any perforated duodenal ulcer.

5.3. Other Circumstances Amenable to Surgical Correction

5.3.1. Blind Loop Syndrome (Candy Cane Deformation at the GEA, “Cloaca” Formation at the JJ Anastomosis)

Not infrequently patients who underwent LRYGB several months to years previously complain of abdominal pain confined to the left upper quadrant together with severe nausea and sometimes dysphagia. This condition is pathognomonic for blind loop syndrome. Diagnosis can be made by barium swallow (to identify a “candy cane” deformation of the blind end of the AL) and/or by CT scan (to diagnose a “cloaca” formation at the level of the Y anastomosis).

Treatment is surgical (laparoscopic) and consists of stapled resection of the redundant part (Figure 13). Care must be taken to avoid excessive narrowing of the lumen, which especially at the GEA may result in increased dysphagia. Stenosis may cause staple line leakage as well.

Figure 13. The candy cane deformity of the blind end at the alimentary limb may become highly symptomatic and demand resection. It is important to pull the uppermost part of the “candy cane” cephalad and to the left rather than to pull on the staple line. Note the presence of a large bore orogastric tube to prevent stenosis.

5.3.2. Intussusception at the JJ Anastomosis

An unusual cause of obstruction is the intussusception at the level of the JJ anastomosis. Mostly the condition consists of the retrograde invagination of the CL into itself and into the JJ anastomosis [41].

The cause is unclear, but one hypothesis is the existence of an active pacemaker in the distal small bowel that sends impulses in a retrograde fashion. Typically these patients will present a typical “target sign” at the abdominal CT scan.

Treatment is surgical (laparoscopic) and quite urgent to avoid necrosis. The best approach consists of plication, or, better, resection and redo of the JJ anastomosis, because simple reduction and fixation is fraught with a high incidence of recurrences.

5.3.3. Internal Hernia

Internal hernia (IH) is a common cause of chronic pain after RYGB. Typically the patient suffers crampoid pain, comparable to contraction pains during labour, most often occurring after a meal. Some patients become emaciated because of this condition.

It is noteworthy that previous closure of the mesenteric and Petersen defect (Figure 2) does not provide fool-proof warranty for absence of IH. In a recent retrospective study performed 9 years after the LRYGB [42], we found that the incidence of small bowel occlusion including IH was a frightening 9%, despite our policy of systematically closing all the defects with non-absorbable suture. Obviously, technical flaws may be responsible for this finding, but it is possible as well that the sometimes massive weight loss creates gaps in an initially well performed closure. Diagnosis in the acute setting is merely clinical: a patient with excruciating pain should be taken to the operating room for emergency laparoscopic exploration. When the cause of the acute abdomen is indeed found to be an IH, some bowel loops will appear dusky (or black!). Often a substantial quantity of intraperitoneal milky-white fluid may be noted, corresponding to chyle, produced by the chronic hyperpressure in the lymphatics of the small bowel.

When reduction of an IH is attempted it is wise to start exploration at the ileo-cecal transition and to gently pull the bowel, passing it from the grasper in one hand to the other, going cephalad, until a “snap” is felt which indicates the reduction of the herniated part. Closure of the defect that caused the IH is usually straightforward after adequate reduction and should be performed by a running suture of non-resorbable suture material.

5.3.4. Excessive Weight Loss and Protein Malnutrition

This condition is quite rare after “regular” RYGB. However, malnutrition is occasionally encountered in some patients who skipped the scheduled follow-up visits, neglected their complaints (of nausea, e.g.) or developed extremely poor eating habits consisting of exclusively ingesting carbohydrates for example. These patients may lose excessive weight and/or develop hypoproteinemia. These individuals invariably present a significantly impaired healing capacity because of malnourishment and are therefore initially best treated by the laparoscopic placement of gastrostomy in the excluded stomach (food stuffs administered via this route will be fully absorbed). After recovery of their metabolic balance these patients will require extensive counseling to address their poor dietary habits, and sometimes will need to undergo corrective surgery which may consist of reversal of their procedure.

5.3.5. Hypoglycemia and Neuroglycopenia

The dramatic impact of RYGB on glucose metabolism, even in the absence of T2DM is well documented. Recently, some attention has been paid to the hypoglycemia syndrome, a condition appearing some 2 to 3 years after the RYGB procedure and characterized by the apparition of hypoglycemia some 90 minutes to 2 hours after a meal (especially after a meal rich in carbohydrates). Hypoglycemia may be accompanied by vague symptoms of light-

headedness, fatigue, exhaustion and marked tremor, but syncopes and epileptic insults are relatively common as well. When neurological symptoms of hypoglycemia become apparent, the syndrome is referred to as neuroglycopenia. This clinical condition is remarkably underestimated and is often confused with “chronic fatigue”, fibromyalgia, or organic central neurological aberrations.

5.3.5.1. Diagnosis

The diagnosis of the hypoglycemia syndrome is essential because this condition may cause car accidents, accidents on the work floor, or in the household. The clinical aspect differs from the dumping syndrome because individuals suffering from hypoglycemia very rarely mention pain and/or diarrhea. Also, the chronology of events differs, the symptoms with the hypoglycemia syndrome occurring later after a meal than with dumping.

Initial diagnosis can be made by a tolerance test with a standard meal or with oral glucose. It is important to record the clinical symptoms that go together with the biochemical hypoglycemia during the test, because some patients do not suffer any symptoms despite plasma glucose values as low as 30 mg/dl. Once the diagnosis of hypoglycemia, which is secondary to an exaggerated insulin response to carbohydrates and sugars, has been made [43], the possibility of an insulin producing pancreatic tumor must be ruled out. The most accurate test available is the sampling of plasma insulin after selective intra-arterial peripancreatic Calcium injections. Intra-arterial Calcium elicits a pancreatic insulin response when a secreting tumor is present. The selectivity of the test allows to detect the approximate location of the tumor in the pancreas. Additional diagnostic tools are the Magnetic Resonance Scan and the Octreotide inhibition test.

5.3.5.2. Treatment

The first treatment of the hypoglycemia syndrome is dietary: patients should refrain from all intake of simple sugars and limit the ingestion of carbohydrates. The requested change in eating behavior is a considerable task, because most patients go through an acute withdrawal phase when kept away from carbohydrates and sugars.

Medical treatment consists of oral acarbose, diazoxide or parenteral octreotide but these treatment modes are expensive and not very efficient [44].

Surgical Treatment

The most effective treatment is surgery. Three types of operations have been described:

- the placement of a band or ring around the pouch to slow down gastric emptying
- pancreatectomy.
- reversal of the procedure

1. Placement of Band around the Stomach Pouch

This treatment was proposed more specifically to address the problem of postprandial dumping [45]. Despite quite good outcomes in terms of dumping reduction, this technique faces the relatively high incidence of complications we already mentioned. Moreover, the technique does not appear to be effective in true postprandial hypoglycemia.

2. Pancreatectomy

Theoretically, pancreatectomy makes sense because it removes the source of insulin secretion. This strategy was first described by Service et al. [46].

Despite good short-term outcomes this very aggressive surgical procedure however does not appear to keep its promises on the long term.

3. Reversal (as mentioned before)

Reversal of the bypass construction is logical because it addresses the alleged cause of insulin hypersecretion, i.e., the bypass of the duodenum, causing an imbalance in incretin production. Some reports however question this approach [47].

There is quite a simple strategy to avoid reversing a bypass for hypoglycemia syndrome in vain. This strategy consists of placing a gastrostomy tube in the remnant stomach, either laparoscopically, or percutaneously, under CT guidance. The patient hereafter is fed exclusively through the gastrostomy. When hypoglycemia clearly regresses (which can be documented by an oral tolerance test through the gastrostomy tube), reversal may safely be attempted. We try to perform full reversal rather than a functional reversal, which may be obtained by gastro-gastrostomy uniting pouch and remnant. Rather, we perform transection of the GEA and of the JJ anastomosis at the level of the BPL ending. The blind end of the AL and of the BPL are reanastomosed, hereby restoring small bowel continuity. Finally, the pouch and remnant are reanastomosed as well, which concludes reversal to a normal anatomy (and may be complemented by sleeve-like gastrectomy). (Figures 3-11)

Figure 14. Algorithm showing the surgical management for Roux-en-Y gastric bypass failures.

CONCLUSION

The laparoscopic Roux-en-Y gastric bypass has passed the test of time and a number of patients have now undergone the procedure more than 10 years ago. Even though the overall

outcomes are excellent, not unexpectedly, some late complications do arise, creating weight problems or other conditions that may be significant in terms of patient comfort and even safety. This chapter attempted at describing the most common problematic issues occurring occasionally after (laparoscopic) Roux-en-Y gastric bypass and to come up with an acceptable strategic approach. (Figure 14).

Chapter 57

FAILED MINIGASTRIC BYPASS: SURGICAL STRATEGIES

Jean-Marc Chevallier*

Department of Bariatric Surgery, Hôpital
Européen Georges Pompidou, Paris, France

ABSTRACT

Against morbid obesity MGB is an alternative to RYGB with less morbidity and same long-term efficiency because it involves just one anastomosis. But the presence of bile in the afferent limb and the 200 cm long bypass imply that MGB failure reoperations must be approached differently than after RYGB. Revision rate is between 0.8 and 4.7% in the literature, 2% in our experience (20/1000).

Revisions are performed for complication (leaks, biliary reflux or marginal ulcer), inadequate weight loss or malnutrition. Leaks after MGB can lead to biliary peritonitis and must be treated quickly by conversion from MGB to RYGB. Intractable bile reflux is rare (0.9%) and must be treated by conversion of the MGB to RYGB, provided the common limb length down to the ileocecal valve is longer than three meters. Insufficient weight loss or weight regain (4.9%) require a multidisciplinary assessment to evaluate eating disorders and to appreciate if there is a true pouch dilatation. If the patient remains morbidly obese and the gastric pouch appears dilated a revision with pouch trimming might be efficient. If the pouch is not dilated a band can be placed around the gastric tube in order to add more restriction.

MGB is more malabsorptive than RYGB but the rate of malnutrition appears low (between 0.3 and 1.28% in the literature). In case of alarming malnutrition a revision can be decided after preparation. Restoration of a normal anatomy can easily be performed after MGB. The conversion of the MGB to a sleeve gastrectomy has a substantial leakage rate but it obviously allows the patient to keep thin.

With experience MGB appears to have a small reoperation rate, to be easily converted or reversible if necessary. It should thus be considered in the armamentarium of bariatric surgeons.

INTRODUCTION

Morbid obesity has become a public health problem in most countries. It leads to a high incidence of complications that decrease life expectancy, even in young adults. Medical treatment of obesity is known to bring disappointing results; however, bariatric surgery has been proved to be efficient for the treatment of morbid obesity, and for decreasing even mortality and complication rates [1]. Our surgical team has 20 years of experience in laparoscopic bariatric surgery. We used to perform the Laparoscopic Roux-en-Y gastric bypass (RYGB) using the Lonröth technique, which consists of an omega loop raised up to the gastric pouch, in which both anastomoses are created and then separated by a section converting the omega into a Roux-en Y gastric bypass [2]. The Laparoscopic Minigastric Bypass or One Anastomosis Gastric bypass (MGB) is a modification of this omega loop bypass, with only one anastomosis, namely the gastrojejunostomy. In 2005, a prospective randomized trial compared MGB to RYGB and showed better outcomes for MGB at 2 years [3]. However MGB has raised criticism and controversy, especially regarding its potential risk of biliary reflux [4]. More recently, some long-term series on MGB have shown promising results in terms of security and efficiency [5-9]. After having published the outcomes of our first 100 MGB procedures [10], we have recently reported on our first 1000 MGB procedures over a 7-year period [11]. We compared these results to the literature and focused in this chapter on surgical strategies in case of MGB failure.

1. THE MGB PROCEDURE (FIGURES 1-2)

All surgical procedures were carried out by six different surgeons using the same standardized technique (Figure 1). Details of the surgical procedure have been published previously [10], and are similar to those described by Rutledge [12].

Figure 1. One anastomosis gastric bypass.

Figure 2. Linear stapled gastrojejunal anastomosis.

A long and narrow gastric tube was created by applying one horizontal 45-mm roticulator Endo-GIA® stapler (Covidien, Cincinnati, OH, US) at the angle of lesser curvature, just above the left branch of the crow's foot, and then four to five vertical 60-mm roticulator Endo-GIA® staple cartridges upward to the angle of His, calibrated along a 32-Fr bougie, similar to the vertical part of a sleeve gastrectomy. No reinforcement was done on the staple line. Section of the greater omentum in bivalve was performed.

The jejunum was mounted antecolically at 200 cm down from the ligament of Treitz, and a side-to-end anastomosis (Figure 2) was performed with the gastric tube using a posterior 45-mm Endo-GIA® stapler and an anterior running suture.

A nasogastric tube was passed into the efferent loop, and a closed vacuum drain was placed behind the anastomosis. The anastomosis was finally checked using an intraoperative methylene blue test.

2. DEFINITION OF FAILURE; REVISION OF AN MGB

In most series weight loss was determined as changes in mean BMI and mean percent Excess Body-Mass Index loss (%EBMIL), with BMI 25 as the upper limit of normal according to the actually adopted standard measure [13].

Failure can be due to complication (marginal ulcer or intractable bile reflux), insufficient weight loss (defined by a %EBMIL of < 25%) or on the opposite, excessive weight loss with malnutrition (%EBMIL > 100% with albuminemia < 30 g/L). Table 1 summarizes late revisions after MGB in four long-term studies.

Table 1. Late revisions after MGB in the literature

	Lee 2012 [14]	Musella [8]	Noun [6]	Chevallier [11]
Inadequate WL	10 (0.9%)	1		4
Bile reflux	4 (0.3%)		4	7
malnutrition	10 (0.9%)	1	4	2
Obstruction	1	1	33 (open)	5
Internal hernia	0	0	0	0
Marginal ulcer	7	4	6	2
stricture	1	0	0	0
TOTAL	33/1322 (2.8%)	7/818 (0.8%)	47/1000 (4.7%)	20/1000 (2%)

WL = weight loss.

Revision rate was between 0,8 and 4.7%. Lee published in 2011 a revision rate of 1.7% on 1322 MGB at 9 years follow up [14]; these data have been updated in 2012 in comparison to RYGB [7]. In this latter paper the two most common reasons for revision were malnutrition and inadequate weight loss in 10 (30,3%), marginal ulcer in 7 (21,2%) and intractable bile reflux in 4 (12,1%) patients. Revisional surgery performed was RYGB in 11 (47.8%), Sleeve Gastrectomy in 10 (43.5%) and conversion to a normal anatomy in 2 (8.6%) patients. In our recently published experience [11] we had to revise 20 patients (2%): 7 for intractable reflux (35%), 5 for intestinal obstruction, 4 for inadequate weight loss, 2 for marginal ulcer, and 2 for malnutrition. The chapter will be divided in three parts: revision for complication, inadequate weight loss and malnutrition.

3. REVISION FOR COMPLICATION

The early complication rate was 6% in the metaanalysis [15], 51 leaks (1%), 2.8% marginal ulcers, 4.2% anemia. Late complications leading to revision are collected in Table 1.

3.1. Leaks

Our 0.6% rate of leakage is low, and is similar to other series [5-9]: this may be because a good blood supply was preserved in the thinner gastric tube and jejunal loop without mesenteric interruption. After MGB leak at the gastrojejunostomy leads to a biliary peritonitis. As for every bariatric procedure in case of leakage the reoperation must be decided as soon as possible, but in the case of MGB it is even more important because of the presence of bile. If the reoperation has been decided soon enough the treatment of the leak can actually be a simple suture, but it has to be accompanied by the conversion of the MGB to a RYGB in order to move the bile away from the gastrojejunostomy (see below).

3.2. Biliary Reflux

Critics of the MGB procedure compare it to the first bypasses performed by Mason in 1969 [16], which consisted of horizontal sectioning of the proximal part of the stomach and

then raising the bowel loop to form an omega shape. The proximity of the anastomosis to the esophagus caused incapacitating biliary reflux, which led the author to abandon the omega procedure for the Roux-en-Y procedure.

Symptomatic biliary reflux is not frequent after MGB and most of the time can be cured medically. In a recent publication [17] we compared postoperative GIQLI (GastroIntestinal Quality of Life Index) 5 years after MGB with preoperative GIQLI. Interestingly we found no significant differences in the GERD symptoms (Regurgitation, heartburn, nausea, belching) between the two groups. Lee reported intractable bile reflux in four cases [7]. In our experience 11 cases of biliary reflux so far necessitated us to convert to a RYGB at ~2 years post-MGB in patients who had lost all their excess weight. The conversion had a spectacular effect on biliary reflux, and patients also maintained their weight loss.

However, GERD is rarely a problem in MGB because the anastomosis is placed low in the stomach. Although it is common to find bile around the anastomosis in the medium- and long-term, it is rarely seen as far up as the esophagus.

MGB actually creates an anatomy where reflux is intuitively promoted, as opposed to the standard RYGB. This is one of the major criticisms raised against the MGB: unfortunately, our data were insufficient to determine if this criticism is unfounded. We can only mention that among the post-operative gastroscopic biopsies conducted, we found foveolar hyperplasia, a sign of biliary reflux, in only 13/76 (17.1%) cases at 2 years and in 2/43 (4.6%) cases at 4 years, with no dysplasia or metaplasia [18].

We have no experience of the anti-reflux technique, as described by others [19]. In our technique the gastric pouch must be long and narrow. Stapling must be vertical, perpendicular to the incision in the pouch, and above the posterior surface of the stomach so that the afferent loop comes from the back, and is higher than the efferent loop. If biliary reflux ever becomes intractable, conversion to RYGB is still a valid and effective straightforward option.

3.3. Marginal Ulcer

One of the classic concerns with a gastrojejunal bypass is the occurrence of marginal ulcers at the edge of the gastrojejunal anastomosis, a condition that is caused by the small gastric pouch continuing to secrete acid. In a recent meta-analysis collecting 5095 cases operated between 1997 and 2011 in seven different centers [15] the marginal ulcer rate was 2.8%. Most of the marginal ulcers appear to be curable medically.

In our experience two ulcers were revealed by symptoms of peritonitis late in follow-up. Both patients were heavy smokers; they had lost all their excess weight, and had stopped taking proton-pump inhibitors. Overall, the number of marginal ulcers (2%) was however low and equivalent to that found after RYGB [20]. The rate of ulcers was probably low because of our policy of preoperatively screening for *Helicobacter Pylori* and eradicating whenever present. The small size of gastric pouches with our technique, and the routine prescription of proton-pump inhibitors most likely helped keeping the incidence as low as well. A larger gastric pouch in MGB (likely producing more acid) might increase the incidence of ulcers; a pouch must be long and narrow to keep the acid secreting volume low. The bile in contact with the anastomosis may actually buffer the ulcerogenic effect of acid on the anastomosis [21].

As for RYGB smoking was a risk factor for marginal ulcers throughout this series We think that patients who continue smoking after an omega-loop bypass need to keep taking proton-pump inhibitors.

3.4. Conversion of MGB to RYGB (Figure 3)

In case of leak or intractable bile reflux MGB can be converted to RYGB. Two techniques are available to convert MGB to RYGB:

- to perform a latero-lateral jejunojejunostomy 70 cm distal to the gastrojejunostomy (Figure 3 A)
- to staple the afferent loop just between both anastomosis (Figure 3B)
- to close the mesenteric defect (Figure 3C)

This technique was proposed by Lee [14] but might be dangerous: because the bypass is already 200 cm long, adding 70 cm results in a 270 cm, which could be too long and lead to malnutrition (see below).

The best approach is to measure the total limb length down from the gastrojejunostomy. If it is more than 3 meters long, Lee's technique may be performed with security. If limb length is less, the following second option should be used.

Figure 3. Conversion MGB to RYGB: easy way (1: jejunojejunostomy, 2: section between both anastomosis).

Figure 3A. Jejunostomy (70 cm distal from gastrojejunal anastomosis).

Figure 3B. Section between both anastomosis.

Figure 3C. Closure of mesenteric defect.

- Resection of the anastomosis
- restoration of the digestive tract by a linear side-to-side enteroenterostomy
- then performing a regular RYGB by transecting the gastric pouch more proximally and constructing a 1.5-meter long alimentary limb (Figure 4).

Figure 4. Conversion MGB to RYGB; regular RYGB. 1: resection of GJ anastomosis. 2: enteroenterostomy. 3: regular RYGB.

4. REVISION FOR INADEQUATE WEIGHT-LOSS

Five percent ($n = 49$) of patients had a $\leq 25\%$ EBMIL and had to be considered weight-loss failures [11]. In this population, the mean preoperative BMI was $42.5 \pm 6.4 \text{ kg/m}^2$ and the %EBMIL was $13.8 \pm 12.6\%$ at 5 years. Noteworthy, 40% of these patients previously had had a gastric banding (LAGB).

Dilatation of the gastric pouch occurred in four patients, which caused excessive weight regain by 24 months post MGB. The dilatation was assessed by an upper GI series. Redo surgery was done by pouch trimming using a calibration tube for all patients, at ~ 4 years post MGB, when patients had a mean BMI of 39.3 kg/m^2 and a mean %EBMIL of 40.3%. There was no per- or post-operative morbidity.

At 5 years, these patients' mean BMI was 35.9 kg/m^2 and %EBMIL was 55.7%. Three of these four patients had had LAGB before MGB.

In front of inadequate weight loss the first question is: is it primary weight loss or weight regain? A psychological and dietetical assessment is mandatory. The multidisciplinary team has to be consulted for an unanimous decision before considering reoperation.

The discussion about weight regain after MGB is not very different from the one after RYGB. Revisional procedures can be either endoscopic or laparoscopic. Considering the potential risk of redo surgery, an endoscopic procedure should be the first choice to improve weight loss. Unfortunately these advanced endoscopic procedures are still under evaluation and not significantly efficient so far [22].

Consequently most of the cases actually are treated by redo surgery.

The choice of the type of surgery should be guided by different factors to limit complications. It has actually been proven that the risk of leakage is more important after redo surgery than after the primary bypass [23].

The local anatomical conditions might influence the decision: previously dissected tissues, sclerosis caused by postoperative leakage can lead the surgeon to avoid stapling or resection. Diabetes resurgence may invite for a more malabsorptive radical solution, such as a distal bypass or a duodenal switch. Conversely, patients who regain weight after initial good weight loss have, most of the time, lost the restrictive part of the bypass.

A regular upper GI series or a 3-D CT-scan volumetry will then assess a pouch dilatation. A pouch over 200 cm³ is considered the threshold to reoperate [24].

Two options are available: pouch trimming or banding.

4.1. Pouch Trimming after MGB Failure (Figure 5)

The restrictive action of MGB is due to a long and narrow gastric pouch, which recently has been considered as the most efficient form of pouch even in RYGB [25]. As with RYGB, pouch trimming may be considered when there is an actual pouch dilatation. If pouch dilatation was due to a technical mishap in the previous operation (incomplete section of the upper fundus too far away from the EG junction) (primary dilatation) trimming the pouch is worthwhile. If dilatation occurred after the operation (secondary dilatation), because of inadequate eating behavior the decision to reoperate is highly dependent on the psycho-dietetical evaluation. Outcomes of reoperation have been reported as good with a primary dilatation, but moderately good after a secondary dilatation.

Reoperation begins by complete adhesiolysis with clear identification of the anastomosis, the biliary and alimentary limbs. The gastric pouch must be dissected off the remnant stomach with freeing of all adhesions of the greater omentum. This usually allows to appreciate the magnitude of the pouch dilatation. The gastric tube has then to be separated from the excluded stomach and the omentum up to the left diaphragmatic crus.

Figure 5. Pouch trimming for weight regain.

This exposes the pouch that can now be resected upwards by a linear Stapler exactly like a "re-sleeve." As in every redo gastric resection it could be advisable to use higher staples (especially in the higher fundus) and/or reinforcement material. A methylene blue test can also be performed to check the staple line.

4.2. To Band a MGB (Figure 6)

If a bypass failure is due to a failure of the restrictive part it is also possible to add some restriction by putting a band around the gastric pouch. This has been reported for RYGB failures and led also Mal Fobi to propose a non-adjustable banded bypass, which led to prolonged weight loss [26].

Some series have shown that putting an adjustable band around the gastric pouch after a RYGB can lead to better weight loss afterwards [27]. Even though this has not been published yet it seems particularly suitable to put a band around the tube of a MGB because this tube is long and even in case of dilated tube there is always room enough to put the band around the stomach above the anastomosis.

The technique is exactly the same as putting a primary band through the pars flaccida. After having opened the pars flaccid of the little omentum, the peritoneal sheet is cut along the edge of the right crus and a retrogastric tunnel is dissected. The posterior dissection reaches the left crus and the band is placed at the upper part of the gastric tube far away from the anastomosis. As there is no longer a lesser sac, the band is not fixed posteriorly. It is then advisable to fix the band to the excluded stomach by three stitches: one above and two beneath the band.

Figure 6. Band on MGB.

5. REVISION FOR MALNUTRITION

Excessive weight loss can be considered as %EBMIL > 100% and albuminemia < 30 g/l.

Rutledge observed malnutrition in 31/2401 patients [12], Noun in 4/1000 [6] and Lee in 9/1322 [14]. In our experience malnutrition occurred in three patients [11]. Their mean BMI at 5 years was 19 kg/m² and %EBMIL was 124% and 122%.

After treatment in a specialized medical unit with parenteral alimentation and psychiatric support, they recently had a reversion of the SAGB into a normal anatomy. The potential risk of malnutrition after MGB occurs because of the long bypassed biliary limb, with consequences depending on the length of the common limb.

5.1. Considerations on "Normal" Limb Length

The "normal" efferent limb length is 592 cm (extremes: 380-790). This means that the length of the intestine can be very variable [28]. It is usually considered that an effective and safe bypass must bypass 1/3 of the total limb length. The regular MGB bypasses 200 cm.

This is adapted if the total limb length is 600 cm. If the efferent limb is only 380 cm long (lowest extreme), this means that the remaining common limb will only be 180 cm long (less than 50% of the efferent limb) which could lead to protein deficiency or malnutrition. If the limb is 790 cm long (highest limit), the bypass will be around ¼, which could be not enough and may lead to insufficient weight loss.

These considerations highlight the fact that it is important, when performing a malabsorptive procedure like MGB, to measure the whole intestinal length from the ileocaecal valve upwards or at least to check that there are still three more meters down from the anastomosis. This also explains why a regular RYGB (which bypasses 150 cm) can lead to failure if the total limb length is 790 cm.

All these considerations do not take into account the villi's surface for each cm² that could be different from one patient to another and decreases with age.

5.2. MGB 'S Risk of Malnutrition

Too short a common limb can lead to protein deficiency and malnutrition whatever the patient eats. One of the criticisms about MGB is that patients may complain of frequent stools, bowel urgency or diarrhea.

Lee [7] reported that, when compared with RYGB, MGB patients had a similar QOL at five years and experienced less abdominal pain but higher stool frequency.

In our experience [17], patients usually have 3 to 4 stools per day during the first 3 months after MGB, and then the rhythm slows down to one or 2 unless when patients continue to consume fats. We compared postoperative GIQLI five years after MGB with preoperative GIQLI.

Interestingly, as demonstrated by Lee, we found no significant differences in diarrhea symptoms between the preoperative and the 5-year's groups. According to the literature the rate of malnutrition after MGB could be between 0.3 and 1.3% (Table 2).

5.3. When to Reoperate?

After a period of incapacitating diarrhea, the albuminemia level falls under 30 g/L. It is important to check the serum prealbumin, showing the lack of protein pooling. The patient has to be hospitalized in a medical unit to check the whole gut and use parenteral nutrition. Most of the time this period of parenteral nutrition improves the nutritional status but when the patient comes back home there may be further deterioration. The recurrence of protein deficiency is an indication to reoperate, especially because parenteral feeding often leads to venous catheter infection.

5.4. Which Revision?

In case of malnutrition after MGB the patient's situation becomes dangerous. The debate is whether it is better to restore the normal anatomy (exposing the patient to return to morbid obesity) or if it is possible to let a secure part of a bariatric procedure (convert the MGB to a Sleeve gastrectomy).

5.4.1. Restoration to a Normal Anatomy (Figure 7)

The MGB can be considered as easily reversible. The restoration of a normal anatomy can be performed by the following consecutive steps:

1. Section of the stomach above the anastomosis (Figure 7 A)
2. Creation of a vertical gastro-gastrostomy (Figure 7B)
3. Restoration of the digestive tract by a linear enteroenterostomy (Figure 7C)
4. Resection of the anastomosis (Figure 7D)

5.4.2. Conversion of a MGB to a Sleeve Gastrectomy

This conversion has been described by Himpens et al., for a RYGB [29]. The difference is that with RYGB a handsewn gastrogastrostomy must be performed between the pouch and the part of the stomach just distal to the horizontal stapling line. This leaves a stomach volume that can be resected at the end of the procedure aided by the use of a 32 or 32-Fch bougie to calibrate the new stomach.

CONCLUSION

MGB is an alternative to RYGB with less morbidity and same long-term efficiency because it involves only one anastomosis.

Table 2. risk of malnutrition after MGB according to literature

	Rutledge [12]	Noun [6]	Lee [7]	Chevallier [11]
N	31/2401	4/1000	9/1322	3/1000
%	1.28%	0,4%	0.6%	0.3%

Figure 7. Restoration of a normal anatomy. (1: section above the gastrjejunostomy, 2: gastrogastric anastomosis, 3: jejunojejunostomy, 4: resection of GJ anastomosis).

Figure 7A. Section above the gastrojejunostomy.

Figure 7B. Gastrogastric anastomosis.

Figure 7C. Jejuno-jejunostomy.

Figure 7D. Resection of gastrojejunal anastomosis.

Nevertheless, the presence of bile in the afferent limb and the 200 cm long bypass imply that MGB failure reoperations must be discussed somehow differently than after RYGB.

* After resuscitation, SG = sleeve gastrectomy, PPI: proton pump inhibitors.

Figure 8. Algorithm for revisional surgery after failed MGB.

Leaks can lead to biliary peritonitis and must be treated by conversion from MGB to RYGB. Intractable bile reflux is rare and must be treated by conversion of the MGB to RYGB, but the common limb length must be longer than 3 meters down to the ileocecal valve. Insufficient weight loss or weight regain may happen. A multidisciplinary assessment must be evaluated if there is pouch dilatation. If the patient remains morbidly obese and the gastric pouch appears dilated, a revision with pouch trimming might be efficient. If the pouch is not dilated, a band can be placed around the gastric tube to add more restriction.

MGB is more malabsorptive than RYGB, but the risk of malnutrition is less than 4%. If the patient is at danger, a revision can be decided after preparation. Restoration of a normal anatomy can easily be performed after MGB.

The conversion of the MGB to a sleeve gastrectomy allows the patient to keep thin but has a higher leakage rate. See algorithm Figure 8. With experience, MGB actually appears to have a small reoperation rate to be easily converted or reversible. It should then be considered in the armamentarium of bariatric surgeons.

ABSTRACT

We are presenting our experience in dealing with patients on whom BPD-DS has caused either excessive malabsorption or insufficient weight loss.

We discuss the decision making to proceed with changing the architecture of the intestinal bypass and what procedure was used to resolve the problem. Suggestions are given on how each procedure was performed and the results obtained from each of these.

In conclusion failure after BPD-DS is relatively rare and revision for denutrition is usually simple and efficient. A complete reversal of the procedure is also feasible.

INTRODUCTION

BPD-DS is a safe and very efficient procedure when follow-up is appropriate. It can but rarely fail by causing either excessive malabsorption or not enough weight loss and will require revisional surgery.

Recently we reported a review of 2615 consecutive patients submitted to a BPD-DS between 1992 and 2010. 95% of these patients were followed up with a visit or blood work within the last 2 years with a mean follow-up of 9.6 years (range 2 to 20 years) [Ref].

We reported that 2.9% (n:78) of these patients required the intestinal diversion be restored either for excessive malabsorption (n:37) or for insufficient weight loss (n:41).

In the present chapter we will focus on these patients and will discuss the type of procedure used. We will first present the possible revisions for malabsorption and then the revisions for insufficient weight loss.

Revision for Malabsorption

BPD-DS by decreasing bile contact with food permanently compromises absorption of fat, liposoluble vitamins and calcium. This is usually easily compensated with appropriate supplements. However by shortening the functional intestine by about half, it temporarily compromises protein absorption in about 20% of the patients for the first year. This is followed by spontaneous recovery for the great majority of patients particularly with appropriate treatment. In a few patients, protein absorption remains under normal levels, and resists to medical treatment. A decision needs to be taken to modify the architecture of the bypass. Circumstances dictate the timing to do so. There is not one perfect timing for reoperation, since it depends on patients' collaboration, easiness of follow-up and severity of patients' symptoms. One needs to keep in mind the risk of hypoalbuminemia on the liver, which may be life threatening when hypoalbuminemia reaches levels below 25g/l. We report our own experience hereunder.

Patient Characteristics

During our 20-years of experience with BPD-DS, a decision was made to modify the bypass in 28 patients and to completely reverse the bypass in 9 (for a prevalence of revision for malabsorption of 1.4%). The reasons that forced the decision to modify the bypass were complex but the dominant factor was recurrent protein deficiency in 15; diarrhea in 8; abdominal pain in 4; persistent anorexia in 7 and persistent asthenia in 3. There were also aggravating factors complicating the situation.

Nine patients were drug addicts, 5 presenting with psychiatric problems, 4 with excessive use of alcohol and in 4 the situation was aggravated by the appearance of concomitant diseases (2 cancers, 1 lupus and 1 cirrhosis). The bypass was almost completely dismantled in 9 patients. This group was younger (38 vs 51 years old) and the decision was delayed (8 vs 4 yrs.) compared to the group whose bypass was only lengthened.

Surgical Approach

In 80% of patients measures of the intestinal segments before revision were found to be within 10% the expected length: Total Alimentary Channel (TAC) 250 cm and Common Channel (CC) 100 cm. In 20% it was found to be longer, with variation in the 50 to 100% range for the TAC and between 100 and 175% for the CC. None of the patients were found with channels shorter than expected. Isolated lengthening of the CC (which is rarely done for diarrhea), can be realized by moving the the ileo-ileal anastomosis upward at the desired level on the TAC channel (Figure 1).

Figure 1. Lengthening only the Common channel. To lengthen only the common channel for controlling diarrhea, the ileo-ileostomy can be displaced more proximally on the total alimentary channel. It implies a mesenteric closure and a new end to side ileo-ileostomy. TAC: Total Alimentary Channel; CC: Common Channel; BC: Biliary Channel.

For lengthening both the TAC and the CC one can either move the distal end of the strict alimentary channel to an appropriate level on the biliary channel (BC) requiring one closure and one anastomosis (Figure 2) or use a "kissing anastomosis method" (side to side) without any closure, between TAC and BC. This technique is easier but leaves a loop in place (Figure 3). In our experience, the lengthening varied from 50 to 300cm for a mean of 100 cm.

On the other hand, 3 different techniques are available to completely or almost completely reverse the intestinal bypass. For complete reversal it is possible to take down the duodeno-ileostomy and to do a new duodeno-duodenal anastomosis with the duodenal-stump, and complete the procedure by replacing the previous latero lateral anastomosis for a new end to end ileo-ileostomy. It requires a closure of the mesenteric window, and 2 new anastomosis (Figure 4). To avoid dissecting the duodenal area and to do an almost complete reversal is possible through two methods.

One technique is to do an end to side ileo-jejunostomy as close as possible from both the duodenal area and the Angle of Treitz at ± 20 cm from each one and replace the initial ileo-ileostomy by a new end to end ileo-ileostomy. It requires a closure of the mesenteric window and 2 anastomosis.

Figure 2. Lengthening both the total alimentary and common channels. The total alimentary channel (TAC) is transected with a mechanical device above the ileo-ileostomy and reanastomosed at an appropriate level on the biliary channel (BC). Both TAC and Common Channel (CC) are lengthened for an equivalent length. The same method can be used for a "nearly complete reversal" if the reanastomosis between the proximal TAC and the proximal jejunum is done as close as possible to the ligament of Treitz.

Figure 3. Kissing anastomoses for lengthening both TAC and CC. A kissing anastomosis (side to side) between TAC and BC forming a loop will lengthen both TAC and BC for an equivalent length. This is the simplest technique and requires only one anastomosis. TAC: Total Alimentary Channel; CC: Common Channel; BC: Biliary Channel.

Figure 4. Complete reversal. The duodeno-ileal anastomosis is taken down and a new duodeno-duodenal anastomosis is done with the duodenal stump. The end of the previous biliary channel is then connected to the origin of the previous total alimentary channel. It requires a mesenteric closure and 2 anastomosis. TAC: Total Alimentary Channel; CC: Common Channel; BC: Biliary Channel.

The other technique consists of using the same approach as for lengthening both the TAC and CC (Figure 2) and to do the reconnection as high as possible to the proximal jejunum close to the angle of Treitz. This requires only one mesenteric window closure and a single anastomosis. With these 3 different methods patients end up with a sleeve gastrectomy with either a normal intestinal tract; or with about 40 to 150 cm biliary bypass. This last method is obviously easier and requires only one small bowel anastomosis. The long-term risk of peptic ulcer is considered negligible.

Results

The lengthening of the intestinal segments was efficient to correct the malabsorption in 80% of the patients. The remaining 20% of patients required re-lengthening or complete reversal of the duodenal switch. In terms of weight gain there was none in one third of the patients, and the other two-third gained 8 to 45 kg. There was one operative death in this group of 37 patients. The mean follow-up after revision was 5.5 years. Late unrelated death was not different than for the whole group. There were 2 suicides (1 and 8 years after revision) and 2 deaths from pulmonary insufficiency (2 and 4 years after revision).

After complete or nearly complete reversal malabsorption ceased and a mean 32 kg weight regain occurred (range: 18 to 74 kg). When the decision for reversal was triggered by the presence of chronic abdominal pain (n:4) this symptomology persisted despite complete revision. There was no major complication following reversal.

Conclusion in Regard to Revision for Malabsorption

The need to surgically correct BPD-DS for excessive weight loss and/or malnutrition was rare (1.4%). It usually occurred in patients presenting with other aggravating factors making the evaluation and the follow-up difficult. It was also precipitated by the appearance of unexpected associated disease. The decision between lengthening the non-bypassed bowel versus a complete reversal depends on the severity of the malnutrition and the difficulty of follow-up. When lengthening is done, it should be done at the expense of the biliary limb and both the common channel and alimentary channel are lengthened: The kissing anastomosis technique is easier because it limits the procedure to only one new anastomosis but the long term risk of creating a loop has not yet been demonstrated.

Lengthening of the alimentary tract usually does not result in major weight gain and relieves the malabsorption in 80% of the patients. A complete reversal removed the malabsorption but was also followed by major weight regain. The surgical technique consisting in joining the distal end of TAC (transected above the ileo-ileostomy) to the proximal jejunum (end-to-side) is easier and leaves the patient with only a duodenal diversion and a 150 cm short bypass.

REVISION FOR INSUFFICIENT WEIGHT LOSS

Patient Characteristics

Definition of "insufficient weight loss" after bariatric surgery is not yet clearly defined. It is generally agreed that a BMI ≥ 40 represents a handicap sufficient in itself to justify surgery, hence we consider failure when a patient with an initial BMI greater than 50 does not reach a BMI below 40 or when a patient with an initial BMI less than 50 does not reach BMI less than 35. This goal is reached in almost 90% of cases after BPD-DS with a mean weight loss of 55 kg. The decision to proceed with a revision for insufficient weight loss depends essentially on patients themselves in relation to the risk involved. In this series, 40 patients required a revision for insufficient weight loss. Revision was performed at a mean 8 years after the primary surgery (range: 1 to 15 years). Overall the group had lost a mean of 31.5 kg; their BMI was 40.3 ± 5.7 ; the gender ratio (f/m) was 31/9 and their mean age 47 years old. Two of them were patients with Prader-Willi syndrome.

Surgical Procedure

In 8 patients, before revision was done, the measurement of both the alimentary and common channel were found to be as expected (250/100 cm); in 14 they were elongated by 20 to 80% and in the other 18, the measures were not reported.

In 13 patients, it was decided to do only a shortening; in 18 only a re-sleeve and in 9 a re-sleeve plus a shortening was performed. When shortening was done the goal was to restore the initial intestinal length (250/100 cm). A segment of the TAC was resected including the

ileo-ileal anastomosis, and a new end to end ileo-ileostomy and a new end to side ileo-ileal anastomosis at 100 cm from the ileo-cecal valve were performed.

RESULTS

One patient suffering from Prader-Willi died early after re-sleeve and shortening. There were 4 late deaths from unrelated causes: (trauma after 10 years, cancer after 16 and 20 years, cerebral vascular accident after 20 years).

After shortening (n:13) an additional 14 kg weight loss (range: 3-38 kg) was obtained, with a follow-up of 8 years and a final total weight loss of 49 kg and final BMI of 34 without protein malabsorption. Only one patient required a second shortening.

Re-sleeve only (n: 18) resulted in additional weight loss similar to shortening of the intestine (19 vs 14 kg) ($p=0.18$). Intestinal shortening accompanied by regastrectomy did not increase weight loss but this addition was undertaken in patients who had already shown greater resistance to weight loss after the initial procedure having lost only 22 kg versus 35 kg for the others. Furthermore this latest group remained with a greater BMI (42 vs 34 kg/m²) and a lower percent excess weight loss (35 vs 63), at a mean 16 years after the initial surgery, confirming their weight loss resistance.

Conclusion Regarding Reoperation to Add Weight Loss

Revision for insufficient weight loss is rarely necessary after BPD-DS (1.6%). If intestinal segments are found within the expected length, a simple regastrectomy would seem the procedure of choice with better additional weight loss. For patients who initially show resistance to weight loss, the addition of a regastrectomy together with shortening of the bowel will almost double the initial weight loss without protein malabsorption. With this strategy a second attempt gave an additional 14 kg weight loss.

CONCLUSION

Lengthening the functional intestine will be efficient to cure protein malabsorption in 80%, and cause minimal weight gain. However 20% of the patients will eventually require a total reversal. For increasing weight loss, regastrectomy was more efficient than shortening of the functional intestine but we believe that when the channels are found to be 50% longer than expected, they should also be shortened and if there is evidence of resistance to weight loss, an attempt to restore the proper length of the bypass is indicated.

²AZ Nikolaas, Sint-Niklaas

ABSTRACT

The failure in weight loss after BPD is an unpleasant event and it is poorly described in the literature: little has been written on the rate of inadequate weight loss, and how to handle it. From the limited available data it seems that after BPD weight loss is less than 50% of the excess weight in about 10% of cases. The solution to this issue varies depending on the eating habits of the patients and on their tolerance to side effects and diet that BPD entails. Surgery can be an eventual solution to weight loss failure but patients should be informed of the small size of the data on which to decide.

1. INTRODUCTION

Insufficient weight loss and weight regain constitute an important problem for all bariatric procedures. The percentages of these problems will vary depending on the different procedures: 50 % or more for adjustable gastric banding (AGB), 20 to 30 % for the standard gastric bypass (SGB), 30 to 50 % for the sleeve gastrectomy (SG). BPD or BPD-DS are still considered the most powerful operation in terms of weight loss, weight maintenance and resolution of co-morbidities. Nevertheless this procedure is not free of failures. There are few data published on this topic, but failures occurred in 8 - 10 % of our patients.

Because of their efficacy malabsorptive procedures are actually considered the most powerful procedure, not only as a primary but especially as a redo procedure after the failure of a restrictive operation [1, 2, 3]. In the author's series weight loss after BPD can be considered very good: at two years a mean BMI of 27 is reached, and the weight loss is sustained, leading to a mean BMI of 28 in the long term. Nevertheless, even BPD can fail in

* Corresponding Author's Email: giuseppe.marinari@gavazzeni.it.

some cases, particularly in long term follow up: since few papers face this problem, it is difficult to estimate at which percentage a failure can happen. In the few papers available the failure rate varies from 1.5% [4] to 10% [5]: as far author's unpublished data, in GMM - VB series in 2.1% of cases the weight loss was less than 25% of the excess weight (EW) and in 8.1% the weight loss was less than 50% of the EW, whilst in LL series, in 2.3% of cases the BMI remained over 35, and 8% regained weight (unpublished data). Goal of this chapter is trying to determine an algorithm to manage a malabsorption failure.

2. REASONS FOR FAILURE

There are three main reasons for failure to loose sufficient weight or for weight regain after BPD.

1. Sweet eating is a pitfall for all type of procedures. Although BPD is a malabsorptive procedure, simple sugars absorption is preserved and there is no restriction in the food intake. This may lead to an extra absorption of hundreds of calories per day, particularly when these sweets are taken in between meals. This drawback must be explained to patients before the operation and must be repeated later during consultation: unfortunately, people sometimes become sweet eater after surgery.
2. Hunger. As in other bariatric procedures, in very early follow up the hunger feeling is diminished after BPD due to the reduced gastric volume and to the change in gut hormones. In contrast with other procedures, while BPD patients are able to eat normal meals early after the operation they usually manage to keep their weight loss. It has been shown that after BPD a threshold mechanism of absorption for fat and starch [6] should allow to eat great amount of food at a stable weight, provided it happens in three-four meals per day. Per meal only 300 til 500 Kcal can be absorbed. Extra meals or grazing will jeopardize this mechanism of weight maintenance: in a BPD series of 15 subjects with Prader Willi Syndrome, where a compulsive hyperphagia is present, half of the patients were failures [7]. After a longer period of follow-up some patients will start to complain of a significant increase in the hunger feeling with polyphagia and hyperphagia, and therefore of weight regain as a consequence. This must be highlighted, because compulsiveness and eating disorders have been suggested as particular indications to BPD, but at the same time they can be reason of a BPD failure.
3. Intestinal adaptation [8], can be a reason of weight regain in a few patients. The diagnosis is difficult and can only be made after exclusion of other reasons (i.e., sweet eating or grazing) of weight regain. It should only occur several years after the operation.

3. TREATMENT

The first step in tackling weight issues after BPD is always an in-depth nutritional counseling in order to evaluate:

- 1) Daily simple sugar intake
- 2) Daily protein intake
- 3) Number of meals per day
- 4) Presence of compulsive hyperphagia

Different causes of weight regain will need different solutions.

- a) Sweet eating. There is no surgical solution in case of pure sweet eating: if the patient cannot control it, the help of a dietician and a psychological support can be offered. Results are strongly dependent on patient compliance
- b) Compulsive hyperphagia. Patients can become very hungry several years after BPD and some of them will start eating several times per day and even during the night. These patients may complain of frequent large stools and weight regain will be an important problem. Psychological support can be offered, but results are in most of the cases disappointing. In case of polyphagia with enough protein intake (> 150 g per day) and normal albuminemia, a surgical solution may be proposed. The resection of the stomach fundus (Figure 1), similar to Sleeve Gastrectomy, can decrease the ghrelin's levels and therefore may induce weight loss (9). Literature is sparse and inaccurate: it is impossible to predict how much of the excess weight can be lost with this type of revisional surgery. The risk of protein malnutrition should always be kept in mind: in this case a further revision to gastric bypass will still be possible. Nevertheless, in LL unpublished data, this type of revision has led to a good weight loss (about 10 points of BMI). In 19 patients the BMI had initially decreased from 46,3 to 27,7 after the BPD. On the long run there was a weight regain to a BMI of 36,3 and a fundus resection was performed. After revision there was an average BMI loss of 10 points down to 25,9. Three patients suffered from protein deficiency and 2 of them needed TPN. Also other authors suggest a secondary Sleeve Gastrectomy as a solution after BPD failure [9].
- c) Intestinal (over)adaptation. When there is no sweet eating, protein intake is adequate (80-100 g/day), eating habits are regular (3, maximal 4 meals per day), and volumes unchanged intestinal (over)adaptation must be ruled out. The solution one may offer is a limb length revision, with shortening of both the alimentary and the common limb. Unfortunately, there is no literature on this subject. There was only a short experience of one of the authors (GMM) at University of Genoa School of Medicine with Scopinaro's series. Shortening the limb length was attempted in 4 cases. The revision was practically ineffective in 3 long term patients and led to a small BMI loss in 1 patient, who had been operated on elsewhere just 18 months before, and in whom the limbs were too long. In analogy with previous reoperations performed for incisional hernias years after standard BPD (alimentary limb cm 200, common limb cm 50) in patients with good weight loss ($> 70\%$ of EW) and good nutritional status, in whom the length of the alimentary and of the common limb was found to be cm 240 and cm 70 respectively, in the 4 cases cited above, the alimentary and the common limb length was shortened to cm 240 and to cm 70 respectively (Figure 2). Revision was uneventful both on bowel movements and on protein levels. Shortening the alimentary and the common limb in order to provide a better weight loss is a big

challenge: an aggressive revision could lead to protein malnutrition and excessive bowel movements, whilst a limited shortening will be ineffective.

Figure 1. Resection of the stomach fundus.

- d) In case of unsatisfactory weight loss in BPD patient with low tolerance, i.e., excessive bowel movements or protein deficiency, a conversion to gastric bypass is feasible (Figure 3). This is quite a drastic intervention since BPD must be taken down altogether and converted into a regular gastric bypass. This includes a subtotal gastrectomy, which makes the operation irreversible. Patients with an intestinal (over)adaptation may be converted into a gastric bypass as well. The early results of conversion are good with an acceptable weight loss, normalization of bowel movements and normalization of vitamin A, E and K; in case of protein malnutrition, serum proteins levels will come to normal values. However, in the longer follow-up, in comparison with a primary gastric bypass, a higher risk of weight regain has been observed. For this reason one of the authors (LL) suggests now a banded gastric bypass, with a silicone ring of 6.5 or 7 cm. Nevertheless, conversion into a gastric bypass is the best solution for patients with BPD side effects: protein malnutrition, excessive bowel movements, vitamin deficiencies, odor problems, other. This conversion can easily be done by laparoscopy, especially in case of previous laparoscopic BPD. In the medium term follow-up the authors found a loss of about 5 points in BMI.

Figure 2. Shortening of the alimentary limb and of the common channel.

Figure 3. Conversion to Roux-en-Y gastric bypass.

CONCLUSION

About 10% of patients after BPD will have an insufficient weight loss or a weight regain. Because of the large burden of nutritional consequences and side effects that malabsorption entails, the number of failures should be reduced by selecting and directing sweet eaters to strategies other than BPD. Nevertheless, some patients will fail in any case, due to compulsive hyperphagia or intestinal adaptation. The first step in finding a solution is a thorough nutritional counseling, and only in very selected cases can a surgical revision be suggested. Compulsive hyperphagia with high daily protein intake can be addressed by a stomach fundus resection, whilst regular eating habits and low tolerance for BPD side effects or for high-protein diet can be addressed by conversion of BPD into a gastric bypass (see Algorithm in Figure 4).

Figure 4. Algorithm for the management of BPD failure.

Before surgical revision of the biliopancreatic diversion patients should be fully informed that:

1. very few data are available on BPD revision;
2. in case of stomach fundus resection the reduced intake of food could lead to protein malnutrition;
3. the conversion to gastric bypass involves a subtotal gastrectomy.

Conversion to gastric bypass is an effective solution for BPD side effects but very little is known about weight effect in the long term.

Chapter 60

HISTORY OF SUBARACHNOID HAEMORRHAGE

Dieter H. Woischneck

Neurosurgical Department, Hospital Landshut, Landshut, Germany

ABSTRACT

The modern definition of an “aneurysm” as being the “dilatation of a weakened artery” originated in 1728 (Lancisis). Cerebral aneurysms were further described by Morgagni (1761) and Biumi (1778) in the 18th century. Beadles (1907) noticed that cerebral aneurysms could in almost all cases only be diagnosed post-mortem. Air encephalography also did nothing to increase diagnostic confidence: the invention of cerebral angiography would be the answer in 1926 (E. Monitz). Seldinger’s catheter method pushed the technology further in 1953. In 1911, Cushing developed a clip for securely occluding inaccessible tumour vessels. McKenzie modified this silver clip and in 1937 Walter Dandy was the first surgeon to treat an intracranial aneurysm with a clip. The first embolisation treatments of intracranial malformations thus resulted in the 1960s and 70s. As a result of international norms the further developments were standardised.

Keywords: history, intracranial aneurysm, subarachnoid hemorrhage, surgical equipment, interventional radiography

Cerebral aneurysms were first described by Morgagni (1761) and Biumi (1778) in the 18th century. The authors had by that time already surmised that subarachnoid haemorrhage was the result of perforated blood vessels. Evidence for this affliction came in 1859: during post-mortem examinations of young men after their sudden deaths, Sir William Gull found haemorrhages in the meshes of the pia mater that had developed as a result of a ruptured aneurysm. However, despite studying these developments methodically the classic triad of symptoms eluded him. The solution was found by Charles Symonds in 1823/24. At the beginning of the 20th century, there then developed a great source of frustration: Beadles (1907) noticed that cerebral aneurysms could in almost all cases only be diagnosed post-mortem. At this stage, surgeons performing craniotomy were by chance confronted with intracranial aneurysms, especially when treating sellar masses. This is evidenced by a report

from Sir Victor Horsley of an incidental finding of an aneurysm in the optic nerve, which he treated with bilateral ligation of the cervical portion of the carotid artery. As the former foremost expert in pituitary gland surgery, Harvey Cushing came across numerous such cases, opening up the sacs (aneurysms) and filling them with muscle tissue. Air encephalography also did nothing to increase diagnostic confidence: the invention of cerebral angiography would be the answer.

ABOUT THE INVENTION AND ESTABLISHMENT OF CEREBRAL ANGIOGRAPHY

In 1926 the Portuguese neurologist Egas Moniz carried out initial experiments into cerebral angiography on dogs, using lithium and strontium bromide as contrast media. When first used in humans this method was by no means successful, causing some patients to die. Surgical exposure of the carotid artery with subsequent direct puncture was carried out for the first time on Patient 6. The examination was technically successful but this patient also died from complications. Cerebral angiography was first survived by a patient on 28 June 1927. The method was published in 1927, and a monograph by the inventor with 180 cases appeared in 1931. Sodium iodide was replaced as a contrast medium in 1931 by Thorotrast. In 1934, Moniz described the four angiographic phases. In 1933, Lima and Caldas published the first results of serial angiography. The angiographic findings for intracranial tumours (Lima) and cerebrovascular aneurysms (Cairns, Dott and Jefferson) were presented at a meeting of the British Society of Neurological Surgeons in 1935.

By the mid-30s, Bergstrand, Olivecrona and Tönnis were presenting angiographic images of arteriovenous malformations. In 1936, percutaneous carotid angiography was described by Lomann and Myerson and disseminated by Shimidzu. In 1940, Takahashi published a study on percutaneous vertebral artery puncture. In Europe, angiography was universally accepted relatively quickly, while in the USA the method was initially received with much scepticism due to issues with the employed contrast agents. This situation was improved through the introduction of tri-iodinated contrast media, leading to widespread use of the method from 1945 onwards. In 1944 Dandy pronounced ambivalent: "There is no doubt whatever of the excellent demonstrations of aneurysms by this method; it is unquestionably the most important, if not the only function that this procedure serves." Even pioneers did not seem to be able to predict the future.

Seldinger's catheter method pushed the technology further (1953). The first embolisation treatments of intracranial malformations thus resulted in the 1960s and 70s. In 1973, computer tomography (CT) was also introduced as a cerebral diagnostic method. First attempts at CT-DSA by Oldendorf (1978) passed off initially without repercussions, and the method became established by the beginning of the 80s.

THE HISTORY OF SURGERY ON CEREBRAL ANEURYSMS

As is often the case, it was in ancient times, around 2725 BC, that Imhotep became somewhat well-known: for arterial aneurysm. There was no further mention until Galen (200

AD). The modern definition of an “aneurysm” as being the “dilatation of a weakened artery” originated in 1728 (Lancisis). The attempt to treat aneurysms through ligation of the proximal artery also dates from this period. In 1760, Jean-Louis Petit reported an aneurysm of the carotid bifurcation that spontaneously healed as a result of thrombosis. These observations led John Hunter, in around 1800, to systematically treat aneurysms by afferent artery ligation with the aim of inducing thrombosis. The method is named “Hunterian Ligation” in his honour. In 1885, Sir Victor Horsley used this principle to treat an aneurysm of the intracranial carotid artery, discovered by chance during a craniotomy, with ligation of the extracranial internal carotid artery. However, the outcomes of incidental findings in the era of carotid ligation that was now beginning were poor. In 1931, Normann Dott was the first surgeon in history to attack a suspected aneurysm after SAH in a planned and targeted way using frontal craniotomy. He had found an aneurysm of the internal carotid artery that he covered with muscle tissue. In the 1930s Harvey Cushing, in particular, attempted to strengthen the wall of the aneurysm (“wrapping”) by removing muscle tissue from the leg. The Silverstone clamp, with which the carotid artery could be gradually closed at the neck, provided an interlude. The aim was to achieve collateral circulation via the circle of Willis prior to final vascular occlusion and thus prevent ischaemic complications of the carotid ligation.

Running parallel to these attempts was the development of aneurysm clips. Initially, it was once again Norman Dott who attempted to ligate intracranial aneurysms through a surgical suture at the neck. This method was favoured time and again up until the late 60s (Brake and Anmacher, 1969). In 1911, Cushing developed a clip for securely occluding inaccessible tumour vessels. McKenzie modified this silver clip and in 1937 Walter Dandy was the first surgeon to treat an intracranial aneurysm with a clip: he treated a 43-year-old, alcoholic man with oculomotor nerve palsy for internal carotid artery aneurysm. The surgical procedure went well, as Cushing reported, even through the brain atrophy. The patient did not have an angiogram prior to surgery. The door was therefore open to the development of ever more specialised clips.

THE DEVELOPMENT OF ANEURYSM CLIPS

The development of clips has repeatedly been referred to as an evolution. The literature certainly gives the impression of a teleological development, which is not exactly evolution. In 1840, in France, the toolmaker Joseph Charrière devised vascular clips that intersected, opened in response to pressure and closed as the pressure decreased. This principle was adopted in the emerging field of neurosurgery: Olivecrona had the idea of attaching further posterior winged blades to the so-called Dandy clip so that the clip could be opened and repositioned. Schwartz developed miniaturised spring forceps as clips. Mayfield continued to develop Schwartz’s inventions in the 1950s by adding a grooved clip surface, kinked introducer and continuing miniaturisation. Together with Kees, an engineer, Mayfield developed a whole range of individual clips. He persuaded seven volunteers to undergo a temporal craniotomy procedure so that he could test his clips *in vivo*. As far as we know from what has been written, there were no deaths. In subsequent years, many details and specifications concerning the clips were presented: The Drake clip had fenestrations for efferent vessels. Mayfield devised clips with arms that did not intersect when closed so that

they would not act like scissors. McFadden devised round clip arms with blunt tips. Heifetz attempted specifically to devise a clip with an additional spring for secure closure. The next generation of clips was then made to the specifications of microneurosurgery (Yasargil, Sugita, Spetzler). Clips were also developed that permit examinations with magnetic resonance imaging.

The success story of clips has also had its darker sides: new developments were often made by companies that had no knowledge of biocompatibility or metallurgy. There were catastrophic results due to clips rusting in the body or lethal complications from magnetic resonance imaging. That improved with the introduction of national standards.

THE INVESTIGATION OF CEREBRAL VASOSPASM

Sir William Gull, who, as already mentioned, was one of the first physicians to attribute SAH to a ruptured aneurysm, was also the first to describe secondary deterioration as a result of cerebral infarctions: 150 years ago, he reported the case of a young woman who fell into a coma five days after suffering SAH, developed wide and fixed pupils, and subsequently died. The post-mortem examination uncovered a ruptured aneurysm of the middle cerebral artery, a blood clot around the vessel and focal softening in the cortex.

THE EXISTENCE OF CEREBRAL VASOSPASM

Physiologists gathered the next findings en route to the discovery of vasospasm: in 1925, Florey described cerebral vasospasms in cats, caused by mechanical and electrical stimulation of the cerebral vessels. In 1944, Zucker found evidence of spasmogenic substances in the serum of laboratory animals. In 1949, Jackson injected blood into the cisterna magna of dogs and assumed that the resulting vasospasm was caused by the components of the red blood cells. The clinical breakthrough in defining “spasm” was made in 1951 by Ecker and Riemenschneider: they detected a spasm in humans using angiography, which was at its strongest at the site of the largest collection of blood, i.e., near the aneurysm. They described the time limitation, reporting that no spasms occurred after day 26 post SAH. This dependence on time led to the realisation by Allcock and Drake in 1965 that the spasm was particularly frequent and pronounced in the first three days after SAH and that the timing of surgery should account for the frequency of the spasm. During this period, Kennedy was the first to develop the theory that a surgical reduction of the SAH volume could lead to spasm prophylaxis. In the 1970s, the existence of cerebral vasospasm and its basic clinical features were recognised, and research into prophylaxis and treatment began:

ABOUT THE PROPHYLAXIS AND TREATMENT OF CEREBRAL VASOSPASM

As early as the 1960s, there were initial clinical recommendations to avoid an excessive drop in blood pressure, even after SAH, in order to improve cerebral perfusion. In 1972, Wise recommended a systolic pressure of 150-170, and a diastolic pressure of 85-100 mm Hg. In the next few years, however, consideration was given to increasing the central venous pressure so as to improve the neurological outcome. The administration of whole blood, plasma or albumin was recommended. Triple-H therapy was in its infancy. In 1979, Allen described the positive effect of calcium antagonists on a vasospasm induced in an experiment on dogs. Allen was also the initiator of nimodipine tests. From then on, treatment of vasospasm played a very influential role in the development of intensive therapy (and vice versa). Questions related to the ventilation strategy and the use or otherwise of invasive neuromonitoring continue to dominate discussions to this day and run parallel to the other major issue of neurosurgical intensive care - neurotraumatology.

In the late 1970s, Weir, Suzuki and Hashimoto established a link between surgical timing and spasm prophylaxis, which is acknowledged today: operations in the first few days after SAH have been found to deliver a better outcome, as the spasm was not yet formed – they are now also regarded as a means of preventing and treating spasms:

SURGICAL TIMING OVER THE DECADES

Until well into the 1950s, the management of ruptured aneurysms was based on case-by-case decisions and personal opinions: in 1951, Slosberg observed that the surgical occlusion of ruptured aneurysms was about as effective as reducing blood pressure with drugs. In 1963, Merritt wrote that ruptured aneurysms should only be approached when operating on space-occupying haematomas. Among the first to recommend surgery, at least for patients in good condition, were Hunt and Hess in 1968. Consequently, they developed a scale for assessing patients after SAH which would make the decision to operate easier. Throughout the 1970s, it was then recognised that after a period of bed rest, drug treatment and stabilisation, better long-term outcomes were achieved with, rather than without surgery. The high rate of later second bleeds could thus be reduced.

In the 1980s, a number of pioneers in aneurysm surgery (Dott, Drake, Yasargil) were still recommending surgery after stabilising the patient, with clipping proving to be significantly better than the wait-and-see attitude alone. However, many patients died while waiting for surgery – not only due to the vasospasm as first described in 1951, but also because of recurring haemorrhages. The improved outcomes of aneurysm surgery were therefore the result of a bias, since the patients with worse baseline conditions or complications were not included in the statistics reported by the surgeons. That was the dichotomy of the 80s: Kasel and Drake complained that although the surgical outcomes had improved, the management outcomes in terms of SAH symptoms had not. Suzuki, Yoshimoto and Norden achieved good surgical outcomes even with early surgery. The International Cooperative Study on the Timing of Aneurysm Surgery recommended early surgery in patients in good condition. It certainly would not have done any harm. In the 90s, early surgery was carried out in patients whose baseline status was poor. Some of the trailblazers of cerebral aneurysm surgery were poor statisticians and fell short with a view to the overall patient population. Retrospectively, this blinkered view of surgical outcomes alone has hampered the advancement of aneurysm treatment. The next expansion of the therapeutic spectrum is also attributable to neurosurgery:

THE DEVELOPMENT OF INTERVENTIONAL NEURORADIOLOGY

The neurosurgeon Luessenhop carried out the first attempts at embolisation on malformations in Washington in 1960. Lehmann used an adhesive substance (cyanoacrylate) for the first time in 1967. In 1973, Djindjian described the embolisation of extracranial tumours and vascular malformations. The rapid technological advancement in X-ray diagnostics was the driving force for interventional neuroradiologists: the ability to visualise the smallest of blood vessels using digital subtraction angiography, “online” imaging in two planes and the development of the flow- or guidewire-directed microcatheter. The wheel of

time is turning very quickly in this medical field: 20 years ago interventional procedures were a rarity, 10 years ago detachable coils did not exist, and five years ago today's stents were a distant reality. The two trailblazers of this technology and their background are presented below:

Fedor Andreevich Serbinenko (1928 – 2002) was a pioneer of embolisation treatment. After completing his studies, Serbinenko joined the N.N. Burdenko Neurosurgery Institute in Moscow in 1954, which was being established at that time as a neurocentre. Supported by the then luminaries of Russian neurosurgery (Shlykov, Salazzkin), he focused his attention on percutaneous angiography. In 1959, during the May Day celebrations in Red Square, he observed how children were playing with helium-filled balloons and trying to steer them like kites on long strings. And so the idea of endovascular balloon embolisation was born. In 1964, his first attempt at balloon occlusion of an intracranial vessel was successful, and in 1969 or 1970 the first permanent occlusion in the case of a malformation was achieved. By 1962, 162 embolisations had taken place, with a valve being developed to prevent spontaneous emptying. Later, Serbinenko worked with Alexander Luria to carry out psychological tests after experimental vascular occlusion. Despite Cold War restrictions, the techniques became more widespread and continued to be developed elsewhere, particularly as doctors from abroad were invited to visit the institute in Moscow. There was one overriding goal: greater individual adaptation to the aneurysm with the embolic agent than with the balloon. It is at this point that the second greatest pioneer in the field appeared: the neurosurgeon Guido Guglielmi, born in Rome in 1948. He took Mullen's idea from the 1960s of using electrolysis to detaching a metallic coil from the catheter, developing it further. Because of its elasticity (memory effect), the coil assumes its original shape and so several coils can be packed into the aneurysm. Stasis and thrombosis occur in the aneurysm as an immediate effect. Epithelialisation to achieve an intact vascular wall is the long-term effect. Guglielmi began his work in Rome in 1976. In 1983, he began working with Fernando Vinuela in London. After many years of correspondence, Vinuela invited him to the UCLA in Los Angeles in 1989, where the GDC (Guglielmi Detachable Coil) was ultimately developed. Guglielmi is now back at work in Rome.

With the dual approach of surgery and embolisation, an interest developed in obtaining more detailed information on a patient's progress in order to achieve a better prediction. The search began for criteria as to which patient would benefit more from which treatment. Attempts then began to describe treatment outcomes on an individual level:

THE EXPLORATION OF HEALTH-RELATED QUALITY OF LIFE

Whilst until the 1990s the treatment outcome of SAH was given as mortality or, more specifically, was categorised according to the Glasgow Outcome Score, since the start of the new millennium many working groups have been exploring health-related quality of life. The quality-of-life research that has now been ongoing for 15 years pursues two goals: 1) The search for sophisticated predictors with which treatment can be optimised individually (intervention yes or no, operation or coiling, expansion or reduction of intensive therapy) and 2) an estimation of the extent to which rehabilitation is feasible. At the beginning of the 2000s, quality-of-life scales from internal medicine or neurotraumatology were used one-for-

one to this end in SAH research. In the last few years, there have been attempts to develop specific tools for measuring the symptoms. What complicates matters is that a lot of statistical data on SAH is subsumed in health and disease registries under the keyword “stroke”, leading to a loss of information on the particular features of the clinical condition. In rehabilitation research, scales are also traditionally used for SAH patients which originate from stroke research and are presumably inadequate.

CONCLUSION

The first modern descriptions of SAH as a pathological condition and cerebrovascular aneurysms were formulated by the neurologists of the 19th century. With the development of neurosurgery in the first half of the 20th century, SAH became a preserve of this new discipline. Hence, therapies were introduced that had been developed from neurosurgery and subsequently opened out into their own disciplines – special intensive therapy and interventional neuroradiology are perfect examples. Neurosurgeons have relinquished their powers at the expense of more individualised treatment. Despite all the medical and technological advances, the clinical experience endemic to neurology and neurosurgery must not be overlooked.

Chapter 61

ARTERIAL AND VENOUS VASCULARISATION OF THE BRAIN

Horst Claassen

Institute of Anatomy and Cell Biology,
Martin Luther University Halle-Wittenberg
Halle (Saale), Germany

ABSTRACT

This chapter has been written especially for neurosurgeons currently in training. To begin with, a description is provided of the cerebral arteries and veins as well as their relevant ramifications. The symptoms of ischaemia will also be mentioned. Thereafter, the neighbouring structures of the cerebral arteries will be described specifically in relation to the surgical treatment of aneurysms. Current textbooks on the subject of anatomy provide functional descriptions of structures often to the detriment of topography, or the two topics are covered together without making any identifiable distinction. In the surgical treatment of aneurysms in particular, it is important to be aware of and possibly avoid damaging the tracts and structures in the immediate vicinity.

Keywords: cerebral arteries, cerebral veins, aneurysms, functional anatomy, topographical anatomy

1. INTRODUCTION

Life-threatening subarachnoid haemorrhage is often the result of a ruptured aneurysm. This type of aneurysm often develops at the bifurcations of the cerebral arteries. Aneurysms, or arterial outpouchings, usually develop due to a congenital structural abnormality of the arterial walls, particularly of the tunica media, or due to the excessive pressure arising from hypertension (Drenckhahn 2004; Bähr and Frotscher 2014). The arteries most commonly affected by such outpouchings are the anterior communicating artery, followed by the internal

carotid artery (Paulsen and Waschke 2010). Post-mortem examinations have revealed the following incidence of aneurysms with advancing age: 4.1% at 20-29 years of age, 11% at 30-49, 8.4% at 50-69, and 20% over the age of 90.

As a preventative measure, aneurysms can be secured with a clip. Otherwise they have to be occluded with a clip if acute subarachnoid haemorrhage occurs. Alternatively, endovascular catheter treatment can be undertaken, by inserting platinum-coated metal coils. This causes a thrombus to form in the saccular bulge of the aneurysm, thereby preventing rupture of the bulging arterial wall. This novel concept is called endovascular coiling. In all cases it is essential to consider the surrounding anatomic structures when performing surgery.

2. ARTERIAL BLOOD SUPPLY TO THE BRAIN

The brain is supplied by two arterial territories, namely the internal carotid artery and the vertebral artery (Figure 1). Corrosion casts of the cerebral arteries illustrate this quite clearly (Tillmann 1997). The cerebral part of the internal carotid artery divides into the anterior and middle cerebral arteries. The intracranial part of the vertebral artery first gives rise to the posterior spinal artery, then the posterior inferior cerebellar artery, and finally the anterior spinal artery. The vertebral arteries then join from both sides to form the basilar artery, from which in each case two further cerebellar arteries emerge: the anterior inferior arteries and the superior cerebellar arteries. Having emitted the superior cerebellar arteries, the basilar artery branches off into the two posterior cerebral arteries.

The posterior communicating artery, which is the penultimate branch of the internal carotid artery, usually anastomoses with the posterior cerebral artery to connect the anterior carotid territory with the posterior vertebral territory. The two anterior cerebral arteries are likewise joined together by a connecting artery, namely the anterior communicating artery. The resulting structure is a closed arterial loop, known as the *circle of Willis*, which encircles the optic chiasm, infundibulum and mamillary bodies (Figure 1). Out of 1,000 brains, however, the circle of Willis as described in textbooks is found only in 53.8% (Leonhardt 1988). Variations appear in 46.2%, often involving the communicating arteries, with the posterior communicating arteries differing more frequently than the anterior communicating artery.

Below is a description of the branches of the major cerebral arteries and the territories they supply, based largely on the observations of Töndury et al. (1987) presented in the Textbook and Atlas of Human Anatomy by Rauber/Kopsch (*Lehrbuch und Atlas der Anatomie des Menschen* Volume III, 1987). The three cerebral arteries are in each case divided into segments, as is customary in neurosurgery. Corning (1923) distinguished between two types of branches in the case of cerebral arteries: 1. The cortical branches which supply blood to the grey matter of the cerebral and cerebellar cortex, and partly ensure perfusion of the semioval centre. 2. The basal branches are small branches that enter the brain vertically and perfuse the “central grey matter”, i.e., the basal ganglia, internal capsule, thalamus, cranial nerve nuclei as well as parts of the semioval centre. An analysis of the structure of the cerebral arteries, including phylogenetic aspects, has been provided by Lasjaunias and colleagues (2001). Yasargil (1969) describes the fine structure of the cerebral arteries. Based on his observations, the middle layers of the intracranial arteries contain far

fewer collagen fibres than the extracranial arteries. This is possibly a factor that predisposes to aneurysms.

Figure 1. Injected specimen showing the arteries of the brain – basal aspect. The blood is supplied to the brain by the internal carotid artery (ICA) and vertebral artery (VA). The two circulations are connected by the posterior communicating arteries (PCoA). The resulting structure is the circle of Willis, which surrounds the optic chiasm, infundibulum and mamillary bodies. The anterior half of the right temporal lobe has been removed from the specimen. The lenticulostriate arteries (LSA), which supply the basal ganglia and internal capsule, are therefore exposed. Note that the lenticulostriate arteries, due to the special preparation technique, hang down from the M1 segment of the middle cerebral artery. These arteries would normally permeate the cerebral matter and ascend toward their supply territories in a formation similar to an onion skin. Also note the ascending posterior inferior cerebellar artery (PICA) on the right, versus the descending posterior inferior cerebellar artery (PICA) on the left. The following major arteries and arterial branches are visible: A1 – A2 = segments of the anterior cerebral artery, AICA = anterior inferior cerebellar artery, ASA = anterior spinal artery, BA = basilar artery, ICA = internal carotid artery, LSA = lenticulostriate artery, M1 – M2 = segments of middle cerebral artery, M2ST = middle cerebral artery of superior trunk, M2IT = middle cerebral artery of inferior trunk, PCA = posterior cerebral artery, PCoA = posterior communicating artery, PICA = posterior inferior cerebellar artery, SCA = superior cerebellar artery, VA = vertebral artery. Image of a wet specimen (1933, Trautmann preparative technique) in a jar (W/D/H 21 x 10 x 26 cm) from the Meckel Collections of the Institute of Anatomy and Cell Biology of Martin Luther University Halle-Wittenberg.

2.1. Branches of the Internal Carotid Artery

The *internal carotid artery* supplies the cerebrum, pituitary gland, orbital content, forehead, as well as the mucous membranes of the frontal sinus cavity, ethmoidal sinuses and anterior nasal cavity. It runs parallel to the pharynx as far as the base of the skull and passes through the carotid canal of the petrosal bone, entering the middle cranial fossa at the pyramidal apex. The artery then traverses the carotid sulcus on both sides of the body of the sphenoid bone and passes through the cavernous sinus. After penetrating the dura mater anteriorly at the sella turcica, it branches off on reaching the subarachnoid space. Next to the sella turcica, the artery curves to form an S shape which is referred to as the “carotid siphon” (Sobotta/Becher 1973). As it carries on, the artery is divided into the following segments:

Cervical Part

At the neck, the interior carotid artery initially lies posterior and lateral to the external carotid artery, but then winds in a more medial direction on its ascent. Immediately before it enters the carotid canal, the artery forms a medial convexity.

Petrous Part

At its petrous part, the interior carotid artery ramifies to supply the tympanic cavity (caroticotympanic arteries). The artery of the pterygoid canal also emerges here, and is anastomosed with the artery of the same name arising from the maxillary artery.

Cavernous Part

At this point the internal carotid artery is surrounded by the venous blood of the cavernous sinus. It releases the following branches:

- Tentorial basal branch
- Tentorial marginal branch
- Meningeal branch to the dura mater of the anterior cranial fossa
- Cavernous branch
- Inferior hypophysial artery
- Branch to trigeminal ganglion
- Branches to cranial nerves IV and V

Cerebral Part

The cerebral part, as it is called, is reached on penetration of the dura mater. It is here where the following arteries emerge, the supply territories of which are described below: superior hypophysial artery, clivus branches, ophthalmic artery, posterior communicating artery, anterior choroidal artery, anterior cerebral artery, middle cerebral artery.

- The superior hypophysial artery leads to the pituitary stalk and the basal hypothalamus.
- The clival branches supply the meninges at the clivus.

- The ophthalmic artery supplies the tear ducts, the eye and the choroid, the ciliary body and iris, as well as the eyelids.
- The posterior communicating artery anastomoses with the posterior cerebral artery and forms part of the cerebral arterial circle (of Willis). The branches of the following are emitted: optic chiasm, oculomotor nerve, thalamus, hypothalamus, tail of caudate nucleus.
- Anterior choroidal artery, runs beneath the optic tract past the lateral geniculate body, arriving at the choroid line through the choroidal fissure of the inferior horn of the lateral ventricle. In vertebrates, this artery once played a pivotal role due to its vast vascular territory. The anterior choroidal artery in humans also has numerous branches, the failure of which, if diagnosable, is not without its problems.

The *anterior choroidal artery* is the final branch of the internal carotid artery before it divides into the anterior and middle cerebral artery. It covers an expansive territory, including parts of the choroid plexus of the lateral ventricle and the third ventricle, the basal ganglia, internal capsule, parts of the diencephalon with the junction boxes for the auditory and optic tracts, as well as portions of the mesencephalon. Damage to the anterior choroidal artery will lead to motor, sensory and visual deficits (Deller 2015). Branches of the anterior choroidal artery:

- Choroidal branches to lateral ventricle, forming the choroid plexus in the inferior horn of the lateral ventricle.
- Choroidal branches to third ventricle, supplying the choroid plexus of the third ventricle.
- Branches to anterior perforated substance, passing through the anterior perforated substance to the genu of the internal capsule.
- Branches to optic tract.
- Branches to lateral geniculate body, the fourth synapse in the visual pathway.
- Branches to internal capsule, leading to the posterior limb of the internal capsule where the pyramidal, optic and auditory pathways, amongst others, are located.
- Branches to globus pallidus, a basal ganglion that is responsible, amongst others, for “more mobility”.
- Branches to tail of caudate nucleus, a basal ganglion.
- Branches to tuber cinereum.
- Branches to hypothalamic nuclei.
- Branches to substantia nigra, a brainstem nucleus that degenerates in the presence of Parkinson’s disease.
- Branches to red nucleus, which plays a central role in extrapyramidal motor function.
- Branches to amygdaloid body, a basal ganglion.
- Anterior cerebral artery = *anterior terminal branch* of the internal carotid artery.
- Middle cerebral artery = *lateral terminal branch* of and continuation of the internal carotid artery.

2.1.1. Anterior Cerebral Artery

A distinction is made between two segments (Figure 1, 2): the precommunicating part (Pars praecommunicalis, or A1 segment) at the base of the brain, and the postcommunicating part (Pars postcommunicalis, or A2 segment) emerging behind the anterior communicating artery.

2.1.1.1. Precommunicating Part (A1 Segment)

- Short central arteries (lateral group): 8-12 branches permeate the medial anterior perforated substance and supply the anterior hypothalamus, column of fornix, anterior commissure, head of caudate nucleus, globus pallidus and anterior limb of the internal capsule.
- Long central artery (recurrent artery of Heubner): this artery leads back to the lateral anterior perforated substance. It supplies the head of the caudate nucleus, the anterior third of the lentiform nucleus, and anterior limb of the internal capsule. *Clinical features:* Long central artery dysfunction can result in aphasia, hemiparesis and paralysis of the muscles of the face and tongue. The artery should be spared when clipping aneurysms (Lang and Wachsmuth 1979).

2.1.1.2. Anterior Communicating Artery

- Short central arteries (anterior group): the anterior group of these arteries form 6-7 narrow ramifications that perfuse the optic chiasm.

2.1.1.3. Postcommunicating Part (A2 Segment)

The postcommunicating part winds around the genu of the corpus callosum, ramifying onto the medial frontal lobe and the cingulate gyrus. Above the corpus callosum, the A2 segment divides into the pericallosal and callosomarginal arteries (Figure 2).

- Pericallosal artery (Figure 2): supplies the corpus callosum and anastomoses at the splenium of the corpus callosum with the posterior cerebral artery.
- Callosomarginal artery (Figure 2): passes over the cingulate gyrus in the cingulate sulcus, ramifying onto the medial surface of the hemisphere.

The cortical branches of the A2 segment not only supply the medial surface of the hemisphere, but also a narrow strip on the lateral surface of the cortex. Close to the superior margin of the cerebral hemisphere, the branches of the A2 segment anastomose with the middle cerebral artery. *Clinical features:* Owing to the described anastomotic processes, both anterior cerebral arteries can, if necessary, be occluded distal to the anterior communicating artery.

2.1.2. Middle Cerebral Artery

The middle cerebral artery (Figure 1) is divided into two segments: the sphenoid part (M1 segment) running parallel to the lesser wing of the sphenoid, and the insular part (M2 segment) ascending in the lateral sulcus. In rare cases, the middle cerebral artery may be

duplicated. Adachi (1928) observed a duplicated middle cerebral artery five times (3%) in 166 hemispheres of donated Japanese bodies.

Figure 2. Injected specimen of the arteries of the brain – medial section. Caudally, the stumps of the internal carotid artery (ICA) and vertebral artery (VA) are visible. The brain is supplied with blood by these two arteries and their ramifications. Note how the supply territories of the anterior cerebral artery (A1 – A2) and posterior cerebral artery (P1 – P4) are connected by the pericallosal artery (PcaA). The following major arteries and arterial branches are identifiable: A1 – A1 = segments of the anterior cerebral artery, AICA = anterior inferior cerebellar artery, SCA = superior cerebellar artery, BA = basilar artery, CmaA = callosomarginal artery, ICA = internal carotid artery, P1 – P4 = segments of the posterior cerebral artery, PcaA = pericallosal artery, PICA = posterior inferior cerebellar artery, VA = vertebral artery. Image of a wet specimen (1957, Trautmann preparative technique) in a jar (W/D/H 22 x 10 x 25 cm) from the Meckel Collections of the Institute of Anatomy and Cell Biology of Martin Luther University Halle-Wittenberg.

2.1.2.1. Sphenoid Part (M1 Segment)

- Anterolateral central arteries (lenticulostriate arteries, Figure 2): these arteries infiltrate the lateral half of the anterior perforated substance, ascending cranially and supplying the putamen, internal capsule, as well as the head and body of the caudate nucleus. *Clinical features:* One branch ascending at the outer aspect of the putamen is referred to as the “artery of cerebral haemorrhage”.

2.1.2.2. Insular Part (M2 Segment)

The M2 segment bifurcates at the limen insulae, or insular threshold, into a superior and inferior trunk (Figure 3).

Figure 3. Injected specimen of the arteries of the brain – lateral view. The branches of the M2 segment of the middle cerebral artery are visible. The M2 segment passes through the Sylvian fissure. The branches of the M2 segment supply, among others, the motor speech centre (Broca's area), the sensorimotor cortex, the primary auditory centre, and the sensory speech centre (Wernicke's area). The following major arteries and arterial branches are visible: AICA = anterior inferior cerebellar artery, ATA = anterior temporal artery, CSA = central sulcal artery, LFbA = lateral frontobasal artery, PTA = posterior temporal artery, SCA = superior cerebellar artery, PPA = posterior parietal (supramarginal) artery. Image of a wet specimen (1957, Trautmann preparative technique) in a jar (W/D/H 22 x 10 x 25 cm) from the Meckel Collections of the Institute of Anatomy and Cell Biology of Martin Luther University Halle-Wittenberg.

- Superior trunk: The arteries of the precentral sulcus, central sulcus (Figure 3) and postcentral sulcus are ramifications of the superior trunk, perfusing the convolutions of the sensorimotor cortex. Further branches supply Broca's area, the motor centre for speech. The supramarginal arteries (Figure 3) and angular gyri lead to Wernicke's area.
- Inferior trunk: The branches of the inferior trunk supply the lateral gyri of the temporal lobe and the primary auditory centre in Heschl's convolutions. The terminal branch of the M2 segment is the posterior temporal artery (Figure 3), which perfuses the majority of Wernicke's area. *Clinical features:* The middle cerebral artery is the largest branch and the continuation of the internal carotid artery. Hence, embolisms from the distal territory of the internal carotid artery are often deposited in the middle cerebral artery (Clara 1959). Occlusion of the posterior temporal artery can affect the sensory speech centre. This artery is therefore also referred to as the "artery of Wernicke's aphasia".

2.2. Branches of the Vertebral Artery

The **vertebral artery** (Figure 1, 2) travels through the foramen of the transverse process of the cervical spine to the atlas, entering the skull through the foramen magnum. Its branches supply blood to the brain stem, cerebellum, the auditory and vestibular system, as well as, via the posterior cerebral artery, the occipital lobe of the telencephalon with visual centre.

2.2.1. Posterior Spinal Artery

The posterior spinal artery is the first intracranial branch of the vertebral artery. It supplies the core areas of the spinobulbar tract.

2.2.2. Posterior Inferior Cerebellar Artery

The posterior inferior cerebellar artery (Figures 1, 2) is the largest branch of the vertebral artery. It supplies the majority of the inferior aspect of the cerebellar hemisphere, the inferior portion of the vermis and core areas of the medulla oblongata. The terminal segment emits the choroidal branch to the fourth ventricle for the choroid plexus of the fourth ventricle.

- Arteries of posterolateral sulcus: the arteries of this lateral vascular system supply parts of the medulla oblongata with the trigeminal nerve nucleus (V) as well as the solitary, ambiguus and dorsal nuclei of the vagus nerve (X) and hypoglossal nucleus. *Clinical features:* A deficit in the lateral vascular system will lead to the development of Wallenberg's syndrome, which is characterised by dysphonia (nerve X), dysphagia (IX), gustatory anaesthesia (VII, IX, X), sensory disorders in the face (V), vertigo and nystagmus (medial longitudinal fasciculus).

2.2.3. Anterior Spinal Artery

The anterior spinal artery (Figure 1) emerges shortly before the confluence of the two vertebral arteries that forms the basilar artery. The pyramidal arteries arising from the anterior spinal artery perfuse the medullary pyramids.

2.2.4. Basilar Artery

At the lower aspect of the pons, the basilar artery (Figures 1, 2) bifurcates, giving way to the anterior inferior cerebellar arteries. Once the superior cerebellar arteries have been discharged at the upper aspect of the pons, the artery divides into a pair of posterior cerebral arteries. The following arteries also emerge:

- Artery of the anterior median fissure: The anterior segment of the pyramidal tract in the lower ventral medulla oblongata is supplied by this artery.
- Medial medullary branches of the anterior median fissure artery: perfusion of the area of the medial longitudinal fasciculus and tectospinal tract in the upper ventral portion of the medulla oblongata.
- Median pontine branches: enter the pons and supply the area of the medial longitudinal fasciculus, tectospinal tract, medial and lateral lemniscus pathways as well as trigeminal lemniscus.

- Short pontine branches: travel into the region of the pontine nuclei and corticospinal tract.
- Labyrinthine artery (though only in 15%; see below).

2.2.5. Anterior Inferior Cerebellar Artery

The anterior inferior cerebellar artery (Figures 1, 2) perfuses the flocculonodular lobe of the cerebellum, and emits a branch to supply the choroid plexus of the fourth ventricle.

- Labyrinthine artery: the artery supplying the auditory and vestibular system is in 85% of cases a branch of the anterior inferior cerebellar artery. Only in 15% of cases does this artery originate from the basilar artery.
- Long pontine branches: lead to the superior cerebellar peduncle as well as to the area of the anterior spinocerebellar tract and the motor nucleus of trigeminal nerve V in the pons.

2.2.6. Superior Cerebellar Artery

The superior cerebellar artery (Figures 1-3) is the largest of the three cerebellar arteries. It supplies the entire superior surface of the cerebellar hemisphere and superior aspect of the vermis. The artery anastomoses with the branches of the inferior cerebellar arteries, and with the posterior cerebral artery in the area of the quadrigeminal bodies.

2.2.7. Posterior Cerebral Artery

The posterior cerebral artery (Figures 1, 2) is divided into four segments. The precommunicating part (P1) is located in front of the posterior communicating artery, with the postcommunicating part (P2) behind. The P2 segment extends as far as the origin of the posterior inferior temporal branch. The quadrigeminal part (P3) begins here, ascending to the quadrigeminal bodies. The terminal part (P4), which winds its way towards the occipital pole, begins at the level of the quadrigeminal bodies.

2.2.7.1. Precommunicating Part (P1 Segment)

- Interpeduncular perforating arteries (posterolateral central arteries): these arteries supply the posterior limb of the internal capsule, the thalamus and hypothalamus, as well as the territories of Perlia's nucleus (oculomotor nerve, III), Edinger-Westphal nucleus and medial longitudinal fasciculus in the mesencephalon. *Clinical features:* A deficit in this arterial segment is described as a peduncular syndrome: homolateral paresis of the eye muscles, contralateral hemianaesthesia, impaired coordination of the eye movements.

2.2.7.2. Postcommunicating Part (P2 Segment)

- Short circumferential arteries: responsible for supplying the red nucleus and substantia nigra.
- Quadrigeminal artery: supplies the quadrigeminal bodies.
- Thalamogeniculate artery: supplies the posterolateral portion of the thalamus.

- Anterior and posterior inferior temporal branches: supply the basal gyri of the temporal lobe. At the hippocampal sulcus, the branches of these arteries form a T-shape bifurcation, thus supplying the hippocampus and dentate gyrus with tiny branches that form an arcade-like pattern. *Clinical features:* Given the vascular architecture, the CA1 region (cornu ammonis 1, Sommer sector) is more susceptible to ischaemia than CA2/CA3 (cornu ammonis 2/3, Spielmeyer sector).

2.2.7.3. Quadrigeminal Part (P3 Segment)

- Lateral and medial posterior choroidal arteries: perfuse the choroid plexus of the third ventricle.

2.2.7.4. Terminal Part (P4 Segment)

- Lateral occipital artery: this artery contributes to the perfusion of the basal surface of the occipital lobe and posterior segments of the temporal lobe.
- Medial occipital artery: the parieto-occipital branch of this artery leads to the superior aspect of the cuneus belonging to the occipital lobe, and the calcarine branch to the pole of the occipital lobe. The visual cortex is perfused in 42% of cases exclusively by the parieto-occipital branch, in 23% by the calcarine branch, and in 31% by both.

3. ANEURYSMS AND NEIGHBOURING STRUCTURES OF THE INTRACRANIAL ARTERIES

3.1. Internal Carotid Artery

Aneurysms of the internal carotid artery (Figures 1, 2) can occur where the artery passes through the cavernous sinus (cavernous part of internal carotid artery) (Duus 1993). The artery curves at this point to form an S shape (carotid siphon) and is surrounded by venous blood. In the immediate vicinity, the following nerves, listed in caudal to cranial order, traverse the sinus wall: maxillary, ophthalmic, trochlear and oculomotor nerves (Sobotta/Becher 1983; Leonhardt 1988). The abducens nerve passes immediately below the artery. A caudally positioned aneurysm will exert pressure on cranial nerves V1, V2, IV and VI. Paraesthesias in the upper and mid face, as well as abducens nerve palsy, can develop as a result. An orally located aneurysm will more likely affect the oculomotor nerve. This can be manifested as a cranial and lateral shift in the position of the eyeball as well as double vision. In addition, the parasympathetic fibres of cranial nerve III may be affected. The pupils will then dilate (mydriasis). An arteriovenous fistula will result from a ruptured aneurysm. In this case, arterial blood will spread via the sphenoparietal and superior petrosal sinuses to more distant sinus cavities.

Aneurysms develop more frequently in the cerebral part of the internal carotid artery, known as the supraclinoid segment (30% according to Bähr and Froscher 2014). These arterial bulges are found near to the ophthalmic or posterior communicating artery

(ophthalmic and posterior communicating aneurysm). Given the proximity to the anterior clinoid process and to the cavernous sinus, it is difficult to operate on such aneurysms (Kyoshima et al. 2006). Secondary involvement of the optic nerve, optic chiasm, or optic tract in the aneurysmal process is possible. If the decussating fibres of the optic chiasm are affected, the nasal fields of the retina, which represent the temporal fields of vision, can be impaired (heteronymous hemianopsia). The field of vision is thus laterally disturbed on both sides. Unilateral impairment of an optic tract will lead to homonymous hemianopsia, causing dysfunction in one temporal and one nasal field of vision.

3.2. Anterior Cerebral Artery

Aneurysms of the anterior cerebral artery (Figures 1, 2) affect the anterior communicating artery in 40%-45% of cases (anterior aneurysm). This artery forms the border between the A1 and A2 segments. An anterior aneurysm is located in front of the optic chiasm. It usually projects superiorly or anteriorly, and less often inferiorly or posteriorly (Sanches-Mejia et al. 2006). Sections of the rhinencephalon such as the olfactory tract and anterior perforated substance are in close proximity. Basal sections of the frontal lobe, such as the rectal gyrus and orbital gyri, likewise border the anterior communicating artery. When operating on this area, it is important to spare the short central arteries and long central artery (both from the A1 segment), which supply the basal ganglia and the internal capsule. Furthermore, the short central arteries (from the anterior communicating artery) supply the optic chiasm. Subarachnoid haemorrhage resulting from a ruptured anterior aneurysm can spread ventrally into the pericallosal cistern and dorsally into the chiasmatic cistern via the cistern of lamina terminalis, which is traversed by the anterior cerebral artery.

3.3. Middle Cerebral Artery

In approx. 20% of cases aneurysms of the middle cerebral artery (Figures 1-3) affect the beginning of the M2 segment (MCA aneurysms according to Bähr and Frotscher 2014). Here, the artery divides into a superior and an inferior trunk. The MCA aneurysm, measuring 2-14 mm, is larger than other types of aneurysm (Rinne et al. 2006). Due to subarachnoid haemorrhage, a ruptured MCA aneurysm more often results in death than other types of ruptured aneurysms. The bleeding may be associated with intraventricular haemorrhage. The inferior horn of the lateral ventricle is affected in such cases. MCA aneurysm is related to the parahippocampal gyrus, as part of the limbic system, and to the amygdala, a basal ganglion. Aneurysmal subarachnoid haemorrhage will spread in the cistern of the lateral fissure, since the M2 segment of the artery passes through the Sylvian fissure (Figure 3). Consideration must therefore be given to the proximity of important telencephalic centres, such as the motor speech centre (Broca's area) in the inferior frontal gyrus, the primary auditory centre in the Heschl convolutions of the superior temporal gyrus, and the sensory speech centre (Wernicke's area) in the supramarginal and angular gyri. On surgical intervention, care must also be taken not to interfere with the branches of the M2 segment that supply the motor and premotor cortex as well as the sensory cortex. Ultimately, the artery does not only bifurcate, namely into the superior and the inferior trunks (Figure 1), but multiple divisions also occur

(Lang and Wachsmuth 1979). If MCA aneurysms are to be occluded, it is important to know about a potential bi-, tri- quad- or pentafurcation so that branches concealed by the side of the aneurysm facing away from the surgeon are not also occluded.

3.4. Posterior Cerebral Artery

Aneurysms of the posterior cerebral artery (Figures 1, 2) are rare and usually affect the postcommunicating P2 segment. This type of aneurysm is found near the oculomotor nerve. Also in close proximity are the cerebral crura of the mesencephalon and parahippocampal gyrus, as part of the limbic system. A subarachnoid haemorrhage will spread into the ambient cistern, which is traversed by the superior cerebellar artery (Figure 2) and the trochlear nerve. Trochlear nerve palsy causes the eyeball to deviate inward and downward.

3.5. Basilar Artery

Basilar artery aneurysms (Figures 1, 2) occur at a rate of 10% (Bähr and Frotscher 2014) in the so-called basilar tip (basilar tip aneurysms), at the upper margin of the pons. The basilar artery divides at this point into the two superior cerebellar arteries and the two posterior cerebral arteries. Immediately ventral to this aneurysm are the mamillary bodies, infundibulum and floor of the hypothalamus. Dorsolaterally, the aneurysm meets with the oculomotor nerve and the fine arteries of the P1 segment (Figure 2) of the posterior cerebral artery that supply the internal capsule and thalamus. A haemorrhage will also spread into the ambient cistern via the interpeduncular cistern. Liliequist's membrane, which extends between the two temporal lobes, prevents the haemorrhage from crossing into the chiasmatic cistern. A basilar tip aneurysm is a space-occupying process in the region of the tentorial incisure (Lang 1985). Compression of the oculomotor nerve is therefore to be expected. The aneurysm can moreover displace the cerebral aqueduct dorsally, and the posterior wall of the third ventricle superiorly (Lang 1985). Intraoperative complications can entail unintentional injury to the fine arteries of the P1 segment of the posterior cerebral artery (Hernesniemi et al. 2006). Damage to one of the small-calibre interpeduncular perforating arteries running through the posterior perforated substance alone can have drastic consequences for the patient (Lawton 2011).

Aneurysms occur less often at the junction of the middle to lower third of the artery, roughly at the level of the origin of the anterior inferior cerebellar artery (1%-2%, according to Bähr and Frotscher 2014), than at the basilar tip (Figure 1). The abducens nerve is found dorsal, and the trigeminal nerve lateral to such aneurysms. Any haemorrhage will spread via the medial pontine cistern into the pontocerebellar cistern, located in the cerebellopontine angle, through which the facial and vestibulocochlear nerves pass. The lateral aperture of the fourth ventricle (Luschka) discharges into the pontocerebellar cistern; adhesion can occur in the event of bleeding. Internal hydrocephalus can result.

Basilar artery aneurysms are difficult to treat surgically on account of the fact that the neighbouring structures of this artery, namely the brain stem, territory of the clivus and tentorial incisure, are very hard to reach from lateral access points in the middle or posterior cranial fossa (Pernkopf 1957). Pterional (where the frontal bone, parietal bone, squamous

bone and greater wing of the sphenoid bone converge), subtemporal and suboccipital approaches are suggested (Hernesniemi et al. 2006). Using modern surgical techniques, such as endovascular coiling of the aneurysm as mentioned at the start, treatment outcomes have improved.

3.6. Anterior Inferior Cerebellar Artery

Aneurysms of the anterior inferior cerebellar artery (Figures 1-3) are rare and are usually found close to the origin of the basilar artery. The abducens nerve is located near to such an aneurysm. The artery runs through the pontocerebellar cistern together with the facial and vestibulocochlear nerves, as well as the labyrinthine artery. The foramen of Luschka also passes into this cistern. Hence, a subarachnoid haemorrhage would also prevent CSF from exiting the lateral aperture of the fourth ventricle (foramen of Luschka). Internal hydrocephalus would be the result.

3.7. Posterior Inferior Cerebellar Artery

Aneurysms of the posterior inferior cerebellar artery (Figures 1, 2) are also rare. They mostly develop where the given artery emerges from the vertebral artery (Figure 1). A distinction is made between the descending and the ascending posterior inferior cerebellar artery (Figure 1). In both cases, the aneurysm is located near the inferior olive and is linked with cranial nerves IX, X, XI and XII (Pernkopf 1957). A subarachnoid haemorrhage will spread into the lateral cerebellomedullary cistern, on the posterolateral aspect of the medulla oblongata. Corresponding membranes separating the adjacent cisterns probably prevent the haemorrhage from infiltrating the pontocerebellar and cerebellomedullary cisterns. During surgical treatment of an aneurysm of the posterior inferior cerebellar artery, occlusion of the small arteries involved in supplying the caudal cranial nerves can occur (Bertalanffy et al. 2006). Wallenberg's syndrome would be the result.

4. VENOUS DRAINAGE OF THE BRAIN

The description of the major cerebral veins and their branches is provided, as with the arteries, on the basis of the relevant chapter by Töndury et al. in the Textbook and Atlas of Human Anatomy by Rauber/Kopsch (1987). With thin walls and no valves, the cerebral veins drain into the dural venous sinuses. They are distributed independently of the arteries and can be divided into two main groups: 1) Superficial cerebral veins: The superficial cerebral veins transport the blood of the cerebral cortex to the superior sagittal sinus and basal sinus. 2) Deep cerebral veins: The deep cerebral veins transport blood from the medulla, basal ganglia and diencephalon to the great cerebral vein (or vein of Galen).

4.1. Superficial Cerebral Veins

The venous blood in the upper half of the outer surface of the cerebral hemispheres flows through the ascending, i.e., superior cerebral veins, into the superior sagittal sinus, and that in the lower half through the descending, i.e., inferior cerebral veins, into the transverse and sphenoparietal sinus. The superficial middle cerebral vein transports venous blood from both territories to the sphenoparietal sinus. Ultimately, the superficial cerebral veins also include the veins of the medial and basal aspects of the cerebral hemisphere.

4.1.1. Superior Cerebral Veins

These are 6-12 ascending veins that can be divided into four groups: frontal, frontoparietal, parietal and occipital veins. The frontal veins drain the blood from the gyri of the frontal lobe. The triad of frontoparietal veins (veins of Rolando) is made up of the precentral, central and postcentral veins. These veins lead into the sulci of the same names and transport the blood away from the precentral and postcentral gyri. The parietal and superior veins transport blood from the parietal lobe and the upper occipital lobe. Characteristically, the frontal veins drain in the direction of the blood flow, whereas the parietal and occipital veins drain in the opposite direction to the flow of the venous blood into the superior sagittal sinus.

4.1.2. Inferior Cerebral Veins

These comprise the inferior temporal and inferior occipital veins, which transport venous blood from the temporal lobe and from the lower occipital lobe down to the transverse sinus. The superficial middle cerebral vein, moreover, which descends through the lateral sulcus to the sphenoparietal sinus, carries blood out of the supramarginal and angular gyri.

The superficial cerebral veins on the outer aspect of the cerebral hemisphere are connected via two important anastomoses: 1. Superior anastomotic vein (vein of Trolard): This vein is formed from the postcentral vein and the superficial middle cerebral vein. It links the superior sagittal sinus to the sphenoparietal sinus. 2. Inferior anastomotic vein (vein of Labbé): This vein facilitates the anastomosis of the largest inferior temporal vein with the superficial middle cerebral vein. Via the vein of Trolard, the superior sagittal sinus is joined with the transverse sinus.

4.1.3. Veins of the Medial Surface

The frontopolar, medial anterior and posterior frontal, paracentral, precuneal veins, and the medial occipital veins drain blood from the territories of the frontal, parietal and occipital lobe belonging to the medial surface. The anterior cerebral (anterior limbic) vein and the dorsal (posterior limbic) vein of corpus callosum transport blood out of the corpus callosum and cingulate gyrus.

4.1.4. Veins of the Basal Surface

The anterior cerebral vein takes the same course as the artery of the same name. The deep middle cerebral artery is found deep in the lateral sulcus under the middle cerebral artery. The basal vein (of Rosenthal) emerges in the territory of the anterior perforated substance from the confluence of the anterior cerebral and deep middle cerebral veins. The vein travels dorsally

along the optic tract, ascending to the quadrigeminal bodies, and discharges into the great cerebral vein (of Galen).

The anterior cerebral veins, the anterior communicating vein, the basal segments of the basal veins and the interpeduncular veins with posterior communicating vein form a cerebral venous circle (also referred to as Trolard's hexagon) beneath the cerebral arterial circle (Figure 1).

4.2. Deep Cerebral Veins

The deep cerebral veins, i.e., the septum pellucidum, thalamostriate and superior choroid veins, drain the blood from the basal ganglia, internal capsule, semioval centre of the white matter and the choroid plexus of the lateral ventricle and third ventricle. They merge at the posterior margin of the interventricular foramen in the anterior venous confluence with the internal cerebral vein.

Figure 4. Aneurysm of the anterior communicating artery (anterior aneurysm). In 40%-45% of cases, the anterior communicating artery is affected. This artery forms the border between the A1 and A2 segments of the anterior cerebral artery. In this case the aneurysm (arrow) projects caudally, which tends to be rare. The aneurysm has ruptured. The subarachnoid haemorrhage has spread into the lamina terminalis cistern and, in particular, into the Sylvian, ambient and pontocerebellar cisterns. Image of an original specimen from a donated body, used in the Neuroanatomy Course at the Institute of Anatomy of Christian Albrechts University Kiel.

The vein of septum pellucidum transports blood from the genu of the corpus callosum, the head of the caudate nucleus and from the white matter of the frontal lobe. Unlike the name suggests, the thalamostriate vein does not drain blood from the thalamus, but rather from the striate body, the internal capsule and the white matter of the frontal and parietal lobe. The superior choroid vein removes blood from the hippocampus, fornix and corpus callosum.

The subependymal veins of the posterior and inferior horns drain blood from the white matter of the parietal and occipital lobe, and the temporal lobe and hippocampus, respectively, transporting it to the basal vein.

The internal cerebral vein takes venous blood from the thalamus, fornix, hippocampus, pineal body and quadrigeminal bodies. The largest thalamic vein, namely the superior thalamic vein, leads vertically into the middle of the internal cerebral artery. The interior cerebral veins on both sides unite via the pineal body to form the great cerebral vein (of Galen).

The great cerebral vein (of Galen) discharges into the right sinus immediately behind the confluence of the inferior sagittal sinus. It incorporates the caudally ascending basal vein (of Rosenthal) and the medial superior cerebellar vein. Furthermore, numerous smaller veins arrive at the great cerebral vein from the territories of the cuneus of the occipital lobe, epithalamus and quadrigeminal bodies.

4.3. Veins of the Cerebellum and Brain Stem

The cerebellar veins follow a similar pattern to the cerebral arteries, though they are independent of the latter. Their larger branches cross furrows and convolutions in a sagittal, and only rarely transverse direction. A differentiation is made between one medial and two lateral groups of veins. The medial veins drain blood from the vermis; the lateral veins remove blood from the cerebellar hemispheres.

The medial superior cerebellar vein carries blood from the upper part of the cerebellar vermis to the great cerebral vein; the medial inferior cerebellar vein transports blood from the inferior vermis to the transverse sinus. The lateral superior cerebellar vein carries the blood of the upper half of the hemisphere to the transverse sinus or straight sinus. The lateral inferior cerebellar vein drains blood from the lower half of the hemisphere, transporting it to the transverse sinus.

The superior petrosal (or Dandy's) vein ascends from the cerebellopontine angle along the trigeminal nerve to the superior petrosal sinus. It removes only a small amount of blood from the cerebellum, since it mainly drains the pons and medulla oblongata. However, this vein can also substitute the lateral superior and inferior cerebellar veins, among others. In this particular case, the superior petrosal vein drains almost the entire cerebellar hemisphere.

The veins of the brain stem are the continuation of the spinal veins, linking them to the basal cerebral veins. Caudally they create a longitudinal and transverse system in a similar way to the spinal veins. Topographically, the veins of the medulla oblongata and pons, like the cerebellar veins, are part of the infratentorial system.

Clinical features: The cerebral veins have specific source territories in which venous stasis can develop in the event of cerebral vein or sinus thrombosis, ultimately resulting in haemorrhagic infarcts in the cortex or medulla, as well as accompanying oedema. Cerebral venous and sinus thromboses are caused not only by thrombi rising from the pelvic and leg

veins, but also by cardiovascular disorders, trauma, tumours, and inflammatory processes in the brain, skull and paranasal sinuses.

Thrombosis leads to an increase in intracranial pressure, and in extreme cases to compression of the tentorium. The consequences are headaches, nausea, vomiting, disorders of consciousness and, depending on the localisation of the pathological process, motor and sensory deficits. Thrombosis of the superior cerebral veins can result in a haemorrhagic infarct, mostly accompanied by contralateral hemiparesis or hemiplegia. Thrombosis of the inferior cerebral veins leads to an infarct in the region of the temporal or basal occipital lobe. The resulting symptoms are aphasia or contralateral homonymous hemianopsia. Thrombosis of the deep cerebral veins causes clouding of consciousness that progresses rapidly and can result in coma.

5. RELEVANCE OF CEREBRAL VEINS AND DURAL VENOUS SINUSES TO SURGICAL ANEURYSM REPAIR

5.1. Superficial Cerebral Veins

When taking a lateral approach, such as for middle cerebral artery aneurysms, attention must be paid to the veins of the Sylvian fissure. The superficial middle cerebral vein courses over the surface together with the branches of the M2 segment of the middle cerebral artery (Figure 3). The deep middle cerebral vein can be found deep in the lateral fissure. At the base of the brain it enters the basal vein (of Rosenthal) along with the anterior cerebral vein. The superficial veins that drain the Sylvian fissure are referred to as “guardians” (Lawton 2011). This structure can vary, draining superiorly, anteriorly or posteriorly (Lawton 2011). In case of superior drainage, the venous blood flows into the frontoparietal veins, the superior anastomotic vein (vein of Trolard), and the superior sagittal sinus. In case of anterior drainage, the blood is discharged into the sphenoparietal, cavernous, superior petrosal and inferior petrosal sinuses. Finally, if the blood is drained posteriorly, it is transported into the inferior temporal veins, inferior anastomotic vein (vein of Labbé), and the transverse sinus.

5.2. Veins of the Cerebellum and Brain Stem

If taking a posterolateral approach through the asterion (junction of the lambdoid, parietomastoid and occipitomastoid sutures), the proximity of the transverse and sigmoid sinuses must first be taken into consideration. The medial inferior and lateral superior cerebellar veins drain the blood from the cerebellar vermis and hemispheres into the transverse sinus. The superior petrosal vein transports blood from the pons and medulla oblongata to the superior petrosal sinus.

ACKNOWLEDGMENTS

I wish to thank Professor Dr. sc. med. R. Schultka, Director of the Meckel Anatomical Collections at the Institute of Anatomy and Cell Biology of Martin Luther University Halle-Wittenberg, for kindly loaning the injected specimens of the cerebral arteries for imaging purposes. I also thank Mr. G. Bothe, photographer at the Institute of Forensic Medicine of Martin Luther University Halle-Wittenberg for the excellent images and expert labelling of the collected specimens.

Chapter 62

NEUROPATHOLOGIE OF SUBARACHNOID HAEMORRHAGE

Angelika Scheuerle

Section Neuropathology, University Ulm, Günzburg, Germany

ABSTRACT

The resulting damages from subarachnoid haemorrhage has a complex pathogenesis encompassing various systems which nevertheless overlap when active simultaneously, consecutively or at staggered intervals. The precise interplay of different factors that lead to alternately pronounced, permanent damage to the central nervous system has not yet been completely and conclusively explained. However, the underlying mechanisms that are activated as a result of bleeding into the subarachnoid space from a blood vessel are presented.

Keywords: subarachnoid haemorrhage, pathogenesis, histology, aneurysm, early and delayed injury

The subarachnoid space is formed by a loosely arranged layer of cells in the pia mater lying next to the glia limitans which is divided by a basal membrane. The outer layer forms densely structured, flat to cuboidal arachnoid cells that are joined with each other by tight junctions. The arachnoid cells have projections which make contact with the pia mater and therefore permeate the space like a spider's web. Individual fibroblasts and collagen fibres, as well as medium-sized blood vessels are also found which, like the intracerebral vessels, have a blood-CSF barrier. The subarachnoid space contains cerebrospinal fluid (CSF) which is transported via the arachnoid villi (arachnoid granulations). If blood penetrates the subarachnoid space, an increase in intracranial pressure, initial vasoparalysis, and impaired CSF drainage will result depending on the extent and magnitude, which will reflect the size of the defect in the vessel. To maintain the cerebral blood flow, the blood pressure will increase along with vasodilation. This leads to an increase in the cerebral blood volume and further increase in intracranial pressure, even global cerebral ischaemia, since the intracranial

pressure will exceed the arterial perfusion pressure. This can be seen in the form of apoptosis but also necroses, both in animal experiments and in post-mortem examinations on humans, whereby apoptosis was not only detected in brain cells but also in vascular wall cells. Vascular wall damage causes a disturbance in the blood-brain barrier with subsequent cerebral oedema and a further increase in intracranial pressure. The death receptor, TNF-alpha, p53, and the Caspase cascade appear to play a crucial role in cell death induced by SAH.

If the acute phase of bleeding is survived, haematoma then develops with lysis of erythrocytes, precipitation of fibrin and infiltration of fibroblasts and sprouting of capillaries, from which granulation tissue forms. These organisational processes explain the course of temporal changes which are reflected in the (CSF “cancel”) histological findings. These initially exhibit fresh blood with perfectly preserved erythrocytes, granulocytes and leukocytes in the same ratio as in a patient’s peripheral blood count. After approx. 12 hours, the erythrocyte boundaries are more indistinct (blurred), and reactive pleocytosis begins. Oxyhaemoglobin and initial erythrophages emerge on the first day post haemorrhage. The breakdown of haemoglobin begins three to four days later with evidence of siderophages. As a result, haematoidin crystals may be visible if there is more pronounced haemorrhaging.

During haemoglobin release and haemoglobin breakdown, oxygen radicals develop, which activate adhesion molecules that attract macrophages and neutrophils. The potent vasoconstrictor leads to the increased detection of TNF-alpha during this phase. Erythrocyte breakdown products in the subarachnoid space can trigger so-called spreading depressions that are linked with the delayed onset of cerebral ischaemia which ensues 5-14 days after the haemorrhage. The slow spread of neuronal (“and glial” cancel) depolarisation detectable on electrophysiological testing can lead to cerebral ischaemia as a result of vasoconstrictive activity.

Figure 1. Structure of the subarachnoid space. From the outside inward, the dura mater is identifiable from the firm collagen/fibre-rich connective tissue with embedded blood vessels. Next is the arachnoid mater with dura-facing neurothelium (arachnoidal cells), from where delicate trabeculae traverse the subarachnoid space like a spider’s web to reach the pia mater, a delicate layer of vascularised connective tissue.

Figure 2. A) Delicate arachnoid mater with narrow, elongated, flat arachnoid cells and embedded blood vessel. B) An adjacent, external band of cortex.

CAUSES OF SAH

Aside from trauma, a ruptured aneurysm (85%) is the main cause of SAH. An aneurysm is the bulging of an arterial wall, the exact origin of which is not yet fully understood. As they are extremely rare in newborn babies and children with no apparent cause (trauma, infections, connective tissue diseases), it is assumed that the change in the vascular wall is acquired. Genetic factors are postulated, since apart from a familial predisposition aneurysms occur increasingly with congenital connective tissue diseases (polycystic kidney disease, Ehler-Danlos syndrome type IV, etc.). Forbes (1930) [1], and later Stehbens (1989) [2], have suggested that a defect appears in the muscle layer at the onset of an aneurysm. Other authors favour the theory that so-called intimal cushions reduced the elasticity locally. This causes increased pressure on the immediately adjacent wall, possibly leading to structural changes in the aneurysm. Calouhi et al. [3] see increasing evidence for an inflammatory event in the pathogenesis of a cerebral aneurysm. Back in 2010, Y. Kanematsu et al. [4] reported that macrophages and cytokines originating from the macrophages assume a key role in haemodynamic blebs. They are particularly effective during the constant remodelling of the wall following haemodynamic stress. It cannot yet be fully understood why some aneurysms rupture, while other aneurysms do not rupture throughout a person's life. Usually, the rupture is assumed to have an inflammatory origin. The risk of rupture grows with the size of the aneurysm, the location of the aneurysm in the posterior circulation, hypertension, alcohol and cocaine abuse.

Histologically, the aneurysm is characterised by the loss of the internal elastic lamina and a thinning or even missing middle coat in the arterial wall, resulting in the wall usually only consisting of collagen fibres, isolated smooth muscle cells and possibly individual elastic fibres. Ruptures usually occur at the dome of the aneurysm where blood and fibrin are deposited. Some fresh and partially organised thrombi are observed in the lumen. Arteriosclerotic changes can take place at the margins of usually fusiform aneurysms.

Aneurysms caused by inflammation are rare and usually accompanied by infectious endocarditis (bacterial or mycotic). Histologically, the bulge in the wall is accompanied by pronounced inflammatory cell infiltrates (granulocytes, lymphocytes).

Morphologically, arterial dissection reveals a tear in the intima and/or media with subsequent bleeding into the arterial wall which, as well as being caused by trauma, can also

be precipitated by amyloid angiopathy. Occasionally, especially in older people and sometimes due to genetic predisposition, deposits of amyloid are found in the walls of the small and medium-sized, mostly arterial blood vessels of the cortex and the leptomeninges. They can be accompanied by Alzheimer's type dementia.

Figure 3. The arachnoid mater follows the invaginated sulcus of the superficial cortex, where it is somewhat fibrosed and the embedded blood vessels are more clearly visible. A small calcified psammoma body can be seen.

Non-aneurysmal perimesencephalic haemorrhage corresponds to bleeding into the basal interpedicular cisterns, anterior to the midbrain. It can occur in combination but also with no evidence of an aneurysm, and is more frequent in hypertensive patients. The patients have an excellent prognosis and require only a short period of convalescence. In particular, no cerebral ischaemia develops.

Figure 4. Recent subarachnoid haemorrhage with well-preserved erythrocytes and individual white blood cells, embedded subarachnoid arterial branch and basal outer cortex are also depicted.

Other rare causes of subarachnoid haemorrhage are arteriovenous malformations of the cerebral cortex which usually lead to an intracerebral haemorrhage and in >5% can bleed primarily into the subarachnoid space. Small aneurysmal bulges of delicate afferent and efferent arterial branches have been identified as a cause of haemorrhage. Cavernomas also more likely lead to intracerebral haemorrhage than to subarachnoid haemorrhage.

SAH develops in 30% of children and most adults with sickle cell disease (Cary et al., 1990) [5]. Other rare causes are venous thrombi, vasculitis, severe stenosis, coagulation disorders, inflammations as well as primary and secondary leptomeningeal tumours.

Figure 5. Less recent subarachnoid haemorrhage (approx. 1 day) with depleted erythrocytes that now have blurry contours.

Figure 6. Incipient signs of organisation of a haemorrhage with erythrophages.

Figure 7. Approx. 1-2 day-old blood with fibrin precipitations, but still loosely distributed leukocytes and interspersed, still well-preserved erythrocytes.

Chapter 63

SUBARACHNOID HAEMORRHAGE

Stefan Röhrer

Department of Neurosurgery, University of Ulm, Ulm, Germany

ABSTRACT

The incidence of aneurysmal subarachnoid hemorrhage is different in miscellaneous countries or regions. Exact global figures are not available. Reasons might be variable medical infrastructure in different countries such as availability of diagnostic methods. Subarachnoid hemorrhage thus could go undiagnosed and a patient may die without prior diagnosis. The common age for subarachnoid hemorrhage is between 40 and 60 years, and women are more affected. Additionally differences between races have been detected in terms of the occurrence of subarachnoid hemorrhage. So black people are statistically more affected. The risk factors for occur of subarachnoid hemorrhage can be separate in modifiable and non-modifiable factors. Examples for modifiable factors are smoking, arterial hypertension and excess alcohol consumption. Familial disposition or genetic diseases are non-modifiable factors.

Keywords: subarachnoid hemorrhage, epidemiology, cerebral aneurysm

EPIDEMIOLOGY OF ANEURYSMAL SUBARACHNOID HAEMORRHAGE

In the literature the incidence of aneurysmal subarachnoid haemorrhage (SAH) in Western countries is quoted as being 6-10 cases per 100,000 inhabitants a year [1, 2]. In some countries, such as Japan or Finland for example, the occurrence of SAH of unknown cause is significantly higher, reaching annual rates of up to 23 out of 100,000 inhabitants [1, 3]. Exact global figures are not available, as the care structure in the various countries does differ significantly. Not everywhere is a standard or emergency CT imaging method available for diagnosing SAH. SAH thus could go undiagnosed and a patient may die without prior diagnosis. An example of this would be Africa. In principle, an aneurysmal SAH can occur at any age, but tends to be more common in people between 40 and 60 years of age [4, 5].

Gender-specific comparison reveals that the ratio between women and men is 3:2 [1]. The risk of SAH was thereby found to be lower in women who do not give birth to their first child until after the age of 23, or who have had hormone replacement therapy but have never taken oral contraception [17].

Furthermore, differences between races have been identified in terms of the occurrence of SAH. Hence, the risk of spontaneous SAH has been found to be 2.1 times higher in black versus white people [6].

Intracranial aneurysms in children are very rare and constitute 1%-5% of all detected aneurysms [14, 15]. A ruptured aneurysm with consecutive aneurysmal SAH causes haemorrhagic stroke in 10%-15% of paediatric patients [16].

RISK FACTORS FOR ANEURYSMAL SUBARACHNOID HAEMORRHAGE

When it comes to the risk factors for aneurysmal SAH, a distinction is made between modifiable and non-modifiable factors.

The modifiable and treatable factors which increase the risk of SAH include smoking (1.9%), arterial hypertension (2.8%) and excess alcohol consumption (4.7%) [3]. The risk of spontaneous SAH is also increased by taking oral contraceptives [7]. As patients with these risk factors are increasingly affected by SAH, acquired damage of the internal elastic lamina appears to be the cause of aneurysm formation.

Predictor for ruptured aneurysm	Points
Hypertension	
No	0
Yes	1
Population	
North America, Europe	0
Japan	3
Finland	5
Age	
<70 years old	0
>70 years old	1

>20 mm	10
History of SAH from another aneurysm	
No	0
Yes	1
Location of aneurysm	
Internal carotid artery	0
Middle cerebral arteries	2
Anterior cerebral arteries/posterior cerebral arteries	3

Figure 1. PHASES Score.

Figure 2. Five-year risk of a cerebral aneurysm rupturing according to the PHASES Score.

The non-modifiable factors include familial disposition, with 5%-20% of all patients having a positive family history of aneurysmal haemorrhage [8]. In particular, first-degree relatives of patients with aneurysmal SAH are found to have a 3-7 times higher risk of also experiencing such a haemorrhage. In contrast, the risk returns to normal in the second generation [9]. There are genetic factors, moreover, that are responsible for the development of aneurysmal SAH. Connective tissue diseases and polycystic kidney disease would be worth mentioning here [10]. In the case of the latter, mutations can be found on chromosomes 4 or 16, depending on the type. In contrast, Ehlers-Danlos syndrome and Marfan syndrome, which are often mentioned in relation to SAH, are only very rarely noted to be associated with a haemorrhage [11] and, in the case of Marfan Syndrome, studies have not established any relevant link [12].

In order to ascertain the five-year risk of a rupture in incidental cerebral aneurysms, the PHASES Score (following Chapter) was developed. To determine the risk of rupture, this score includes age, arterial hypertension, size and location of the aneurysm, previous history of SAH and the geographic location of the patient [13].

Chapter 64

RISK FACTORS: FORMATION, GROWTH, RUPTURE

Karl-Michael Schebesch and Petra Schödel

Neurochirurgische Klinik, University of Regensburg,
Regensburg, Germany

ABSTRACT

Aneurysms have a pathology that is certainly multifactorial and probably an expression of genetic predisposition. Their incidence is increased in the event of a family history, and they usually occur in considerable numbers with certain genetic diseases. Arterial hypertension, diabetes mellitus, smoking, drug abuse and connective tissue diseases with tunica media insufficiency are suspected risk factors for aneurysm formation. A distinction must be made between the factors that promote the development of cerebral aneurysms and those that cause them to rupture and lead to the occurrence of subarachnoid haemorrhage. In addition to age and sex, size, morphology, positive history of a previous ruptured aneurysm, as well as a positive family history are other significant contributory risk factors for a rupture.

FORMATION

Recent autopsy studies, along with radiological screening, have demonstrated that the prevalence of cerebral aneurysms is in some instances much higher than previously assumed [1, 2]. Aneurysms have a pathology that is certainly multifactorial and probably an expression of genetic predisposition [3, 4]. Their incidence is increased in the event of a family history, and they usually occur in considerable numbers with certain genetic diseases (polycystic kidneys, Marfan syndrome, Ehler's Danlos syndrome) [1, 5, 6]. The following factors are suspected to contribute to the development and growth of cerebral aneurysms: arterial hypertension, diabetes mellitus, smoking, drug abuse and connective tissue diseases with tunica media insufficiency [4, 5, 7].

Elaborate computer-based simulation studies, as well as physical wind tunnel experiments, have to date produced valuable yet inconsistent results which when combined, however, suggest that considerable influence is exerted by the properties of the vessel walls – such as shear stress in the vascular walls, the angle of the exiting vessels and the surrounding pressure. Pathohistological studies of aneurysm-carrying vessels have also demonstrated that a sometimes pronounced inflammatory reaction takes place in the vascular wall, accompanied by an influx of T cells and macrophages. It is therefore presumed that the localised weakening of the vessel wall, together with the flow characteristics of the blood, could result in the formation of cerebral aneurysms [8-10].

Table 1. Phases Score: Predicted risk of rupture in percent within the next 5 years.

GROWTH AND RUPTURE

A distinction must be made between the factors that promote the development of cerebral aneurysms (see above) and those that cause them to rupture and lead to the occurrence of subarachnoid haemorrhage (SAH). As a condition, SAH peaks between the ages of 50 and 70 years, and affects women approx. 1.6 times more often than men. In addition to age and sex, however, there are other significant contributory factors, of which the following have been

frequently identified: size (craniocaudal diameter or largest diameter) depending on anatomic position (e.g., >5 mm ACOM, >7 mm ICA/MCA/PCOM), morphology (irregular, fusiform, blebs, blisters), positive history of a previous ruptured aneurysm, as well as a positive family history [7, 11-13].

The role of environmental factors such as the weather is not clear, whereas ethnicity has been confirmed as a definite and highly significant factor. Hence, the incidence of aneurysmal SAH in Asia, but also in Finland, is approximately three times higher than in Central and Western Europe [7, 11-13].

A practical risk stratification method for use in patients with cerebral aneurysm is the PHASES score, which accounts for the aforementioned variables and permits estimation of the haemorrhagic risk [14].

Mycotic aneurysms (following cerebral infections), dissecting aneurysms (usually caused by trauma) and giant aneurysms (>24.9 mm) are rare cerebral aneurysmal malformations. These three entities are to be viewed as having a distinct pathophysiology in terms of development and risk of rupture, and according to a number of authors are to be strictly separated from conventional cerebral aneurysms [6, 7, 12, 13].

Chapter 65

SCALES

Petra Schödel and Karl-Michael Schebesch

Neurochirurgische Klinik,
University of Regensburg, Regensburg, Germany

ABSTRACT

There is a variety of scales that have been established specifically for grading Subarachnoid Haemorrhage. Initial assessment of the level of consciousness is made by the Glasgow Coma Scale. The scales most commonly used for grading SAH are those by Hunt and Hess and the World Federation of Neurological Surgeons. Imaging-based classification systems are represented by the Fisher Rating Scale and Modified Fisher Rating Scale. Volume and distribution of the blood in the initial computed tomography are rated. To describe the outcome objectively, the Glasgow Outcome Score is often used.

The severity and the prognosis of subarachnoid haemorrhage are determined using a variety of scales that have been established specifically for grading SAH [1].

An initial preclinical assessment of the level of consciousness is made using the Glasgow Coma Scale (GCS, see Table 1) [2]. This scale was developed in 1974 by neurosurgeons Graham Teasdale and Bryan Jennett as a means of generally estimating the depth of unconsciousness, and has since become established in emergency medicine worldwide. Owing to its routine use, it is not only neurosurgeons that have become highly proficient in its application. The initially measured GCS score is integrated into other scores specific to SAH. Furthermore, by regularly measuring the GCS it is easy to detect a change in the level of consciousness, such as during the vasospastic phase.

The scales most commonly used for grading SAH are those by Hunt and Hess (HH, see Table 2) and the “World Federation of Neurological Surgeons” (WFNS, Table 3) [3, 4].

Table 1. Glasgow Coma Scale

Glasgow Coma Scale (GCS)		
<i>Eye opening</i>	Spontaneous	4
	In response to voice	3
	In response to painful stimulus	2
	No response	1
<i>Verbal response</i>	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
<i>Motor response</i>	None	1
	Obeys commands	6
	Localised defence	5
	Withdrawal	4
	Flexion	3
	Extension	2
	None	1
Total (GCS score)		3-15

Table 2. Hunt and Hess Scale

Hunt and Hess grading		
<i>Grade</i>	<i>Consciousness</i>	<i>Clinical severity</i>
0	Awake	Asymptomatic, incidental
I	Awake	Asymptomatic, mild headache, discrete nuchal rigidity
Ia	Awake	Fixed neurological deficit with no further evidence of SAH
II	Awake	Severe headaches, nuchal rigidity, cranial nerve deficits, no further focal neurological deficit
III	Somnolent	Confusion, slight focal neurological deficit
IV	Soporific	Moderate to severe hemiparesis, onset of decerebrate rigidity, vegetative disorders
V	Deep coma	Signs of decerebrate rigidity

Table 3. World Federation of Neurological Surgeons Grading System (WFNS Scale)

World Federation of Neurological Surgeons Grading System		
<i>Grade</i>	<i>GCS</i>	<i>Motor deficit (hemiparesis, aphasia)</i>
I	15	No
II	13-14	No
III	13-14	Yes
IV	7-12	Yes/No
V	3-6	Yes/No

Hunt and Hess developed their classification system in 1968 based on 275 SAH patients, in whom they identified a correlation between the initial neurological condition and the severity of the disease course. The patients are stratified on the basis of their initial neurological symptoms, from asymptomatic, mild headache (HH I) to deep coma (HH V). Significant pre-existing conditions, as well as any vasospasm already detectable on an

angiogram, will lead to the patient being placed in the next highest HH category. The higher the Hunt and Hess score, the greater the probability of death and a poor neurological outcome, therefore. The original publication describes an increase in the mortality rate from 11% at grade HH I to 100% at HH V. Modern, rapid diagnostic tests and critical care have vastly improved the prognosis of patients whose baseline neurological condition is poor. A recent publication reports a good outcome in 26% of SAH cases rated WFNS V (see below) compared to a mortality rate of 30% in the past [5]. The Hunt and Hess Scale was modified in 1974 with the addition of grades HH 0 (unruptured aneurysm) and HH Ia (no meningeal reaction, but fixed neurological deficit, e.g., oculomotor nerve palsy) [6].

Table 4. Fisher Rating Scale

Fisher grading	
Group	Evidence of blood on CCT
1	No evidence of blood
2	Diffuse distribution of blood or evidence of blood in the subarachnoid space, including interhemispheric fissure, insular cisterns or ambient cisterns less than 1 mm thick
3	Localised blood clot and/or evidence of blood in the subarachnoid space more than 1 mm thick
4	Intracerebral or intraventricular blood with diffuse or no SAH

To improve the objective assessment of the severity of SAH, the WFNS Scale was developed in 1988. Stratification is achieved by grading the level of consciousness of the patient based on the GCS, as well as any possible motor deficit.

Table 5. Modified Fisher Rating Scale

Modified Fisher					
Group	No SAH	Focal or diffuse, thin SAH	Focal or diffuse, thick SAH	Intraventricular SAH	
0	+	-	-	-	No subarachnoid or intraventricular blood
1	-	+	-	-	Thin, diffuse or focal SAH, no intraventricular blood
2	-	+	-	+	Thin, diffuse or focal SAH with intraventricular blood
3	-	-	+	-	Thick, diffuse or focal SAH, no intraventricular blood
4	-	-	+	+	Thick, diffuse or focal SAH with intraventricular blood

In addition to rating SAH severity clinically, there are also imaging-based classification systems. Grading in this case is mostly undertaken using the Fisher Rating Scale (Table 4) and Modified Fisher Rating Scale (Table 5) [7, 8]. The volume and distribution of the blood in the initial CCT can certainly act as predictors for the occurrence of clinically relevant vasospasm, and thus correlate with a poor neurological outcome. Assignment to Fisher 4 with intraparenchymal or intraventricular blood thus implies the highest risk of vasospasm.

Table 6. Glasgow Outcome Scale

Glasgow Outcome Score		
Grade		Clinical description
1	Death	Severe injury or death without recovering consciousness
2	Persistent vegetative status	Severe damage with prolonged state of unresponsiveness and a lack of higher mental functions
3	Severe disability	Severe injury with permanent need for help with activities of daily living
4	Moderate disability	No need for assistance in everyday life, employment is possible but may require special equipment
5	(Almost) complete recovery	Slight damage with minor neurological and psychological deficits

To describe the outcome objectively, the Glasgow Outcome Score (GOS, see Table 6) is often used in patients with SAH as well as in other patients with brain injuries [9]. The degree of disability in the patient that results from the effects of SAH are thus described, but the neurological deficits are not precisely differentiated. Moreover, the GOS only inadequately determines psychological disorders and cognitive impairment.

In addition to the SAH classification systems described above, there are others which in everyday practice are used only seldom or only on a regional level. Those of particular interest are the Claassen CT Rating Scale, which describes the distribution of the blood on CCT in greater detail than the Fisher Grade and likewise permits estimation of the risk of vasospasm, and the SAH grading system developed by Ogilvy and Carter in 1998. Patient age, HH grade, Fisher grade and aneurysm size are thereby included in these assessments. Both scales permit a slightly more exact risk estimation but are far more complicated to use and to analyse [10, 11].

Chapter 66

SYMPTOMS, EXTRACRANIAL MANIFESTATIONS

Petra Schödel and Karl-Michael Schebesch

Neurochirurgische Klinik,
University of Regensburg, Regensburg, Germany

ABSTRACT

The sudden development of intense headache (thunderclap headache) is usually the first symptom of aneurysmal subarachnoid haemorrhage: “worst headache of my life.” The headaches are often accompanied by clouding of consciousness and even coma. Loss of consciousness can be just temporary following Subarachnoid Haemorrhage, but can also result in persistent coma and even death. Nuchal rigidity is one of the key symptoms. Localised pressure resulting from a ruptured aneurysm as well as an innocent aneurysm can lead to cranial nerve deficits. Depending on its location and extent of an intracerebral haemorrhage it can lead to focal neurological deficits such as hemiparesis or aphasia, as well as epileptic seizures. However, there are a certain number of more rare extracranial symptoms.

The sudden development of intense headache (thunderclap headache) is usually the first symptom of aneurysmal subarachnoid haemorrhage [1]. This type of headache will even be described by migraine patients as the “worst headache of my life” or the “feeling that my skull is being split in two by an axe.” Retrospectively, approximately 30%-40% of patients report headaches of increased intensity in the preceding weeks which are interpreted as being related to mild SAH (“warning bleed”) or a growing aneurysm [2, 3]. In addition to a thunderclap headache, severe nuchalgia and occasionally back pain along the entire length of the spine can also develop.

The headaches are often accompanied by clouding of consciousness and even coma. They can be caused by increased intracranial pressure, acute hydrocephalus, direct parenchymal brain damage from intracerebral bleeding or ischaemia associated with SAH, or even seizures. This loss of consciousness can be just temporary following SAH, but can also result in persistent coma and even death. Secondary clouding of consciousness over the

course of the disease can be an expression of secondary haemorrhage, or also increased intracranial pressure with CSF stasis.

Clinical examination of the patient will usually reveal marked nuchal rigidity not long after SAH. Meningeal irritation is indicated by the patient's avoidance of light and sensitivity to noise. Nausea and vomiting can also occur. The Lasègue, Kernig and Brudzinski signs may be positive.

Given the close proximity of the cranial nerves and arteries of the circle of Willis, localised pressure resulting from a ruptured aneurysm as well as an innocent aneurysm can lead to cranial nerve deficits. There have been reports in particular of oculomotor nerve palsy from aneurysms in the left and right posterior communicating artery, abducens nerve palsy from aneurysms in the cavernous sinus, or scotomas from large aneurysms in the internal carotid artery or anterior communicating artery.

A ruptured aneurysm causes intracerebral bleeding, which depending on its location and extent can lead to focal neurological deficits such as hemiparesis or aphasia, as well as epileptic seizures.

Ocular bleeding, especially into the vitreous body, is likely to occur as a result of stasis in the intraocular veins which arises due to an increase in intracranial pressure during and after the aneurysm has ruptured. This condition, known as Terson syndrome, is found in approx. 10%-20% of all SAH patients and is associated with a higher rate of mortality. If visual disorders develop due to Terson syndrome, vitrectomy may be necessary over the course [4, 5].

In addition to all these symptoms, which result from changes in the brain and dura precipitated by the aneurysm and SAH, there are a certain number of more rare extracranial symptoms.

Cardiac problems of any nature are a secondary symptom of SAH and occur in approx. 14% of patients. From basic ECG changes to tachyarrhythmias and bradyarrhythmias, and even elevated troponin and heart attacks - anything is possible [6]. A rare cardiac complication is Takotsubo-like cardiomyopathy, which probably develops due to increased catecholamine release during the acute phase of SAH [7]. This left-ventricular dyskinesia abates as a rule after a few weeks. Neurogenic pulmonary oedema can develop from SAH-induced cardiac dysfunction, but also from treatment-related hypervolaemia. Furthermore, hyperglycaemia and marked electrolyte disorders, such as hyponatraemia and hypokalaemia, can result from SAH [8].

Chapter 67

ADMISSION, DIAGNOSTIC IMAGING, ACUTE HYDROCEPHALUS

Thomas Schmidt

Department of Neurosurgery, Evangelic Hospital Oldenburg,
Medical Campus University of Oldenburg, Germany

ABSTRACT

A patient with subarachnoid haemorrhage can be at extremely high risk on the clinical spectrum or appear to be almost asymptomatic on admission. Medical management must be able to quickly adapt to this clinical scenario and the rapid progression of the condition that under certain circumstances can occur. Therefore, the neurological and radiological scales for evaluating patients with subarachnoid haemorrhage should be used routinely. The life-threatening complications that accompany subarachnoid haemorrhage must be immediately identified, corrected, and avoided with a view to rebleeding from the ruptured haemorrhage. Modern methods of computed tomography permit diagnosis of subarachnoid haemorrhage in the first few hours after onset of the symptoms in particular. A non-aneurysmal cause for spontaneous subarachnoid haemorrhage is found in only 15% of cases.

Keywords: grading scales, diagnostic imaging, aneurysm rerupture, acute hydrocephalus, epileptic seizures

INITIAL NEUROCRITICAL CARE – MEDICAL EVALUATION

Patients with suspected or proven subarachnoid haemorrhage admitted to a neurovascular unit should immediately undergo targeted neurological evaluation to determine the scope and urgency of further diagnostic and therapeutic efforts. Initial management involves primary clinical stabilisation of the patient, ascertainment of the correct diagnosis, definitive treatment of the aneurysm and avoidance of complications. If patients have survived the first few hours of subarachnoid haemorrhage, they are subsequently at risk of three major neurological

complications: rebleeding of the ruptured aneurysm, acute hydrocephalus, and delayed cerebral ischaemia.

Once the patient has been admitted, attention should first be given to his/her level of consciousness and any neurological deficits. At this point about half of the patients are already comatose. [1, 2] The loss of consciousness at onset of the symptoms is also a strong indication of a ruptured aneurysm and does not typically occur in perimesencephalic subarachnoid haemorrhage. [3] These patients are at risk of respiratory failure. Intubation and mechanical ventilation should ensure adequate oxygenation, maintain the pH in the normal range and prevent hypercapnia.

Alert patients usually describe the headaches as the worst they have ever had in their lives, focussing in particular on their extremely sudden onset. A preceding “sentinel” headache is reported by 10% to 43% of patients. [4] The headaches are mostly associated with one or more concomitant symptoms including nausea and vomiting, meningism, temporary loss of consciousness, cranial nerve disorders and neurological deficits.

Grading Scales

The initial clinical severity of subarachnoid haemorrhage is in itself a significant predictor for the outcome of the condition. [5] The severity should therefore be clinically determined as soon as possible using the Glasgow Coma Scale [6], the Hunt and Hess Scale [7], and the WFNS Scale [8]. Whereas the GCS is used to judge the clinical level of consciousness regardless of the underlying cause, the HH and WFNS scales were developed specifically for clinically stratifying SAH (Following Chapter). Use of these scales provides a clear clinical determination of the patients condition, whilst the parameters of the HH Scale are influenced heavily by the examiner’s subjective opinion.

The Fischer Scale [9] was developed as a means of assessing the risk of vasospasm and cerebral ischaemia from baseline CCT. The subsequently adapted and less subjective Modified Fisher Scale [10] evaluates the volume of cisternal and intraventricular blood more specifically as part of its risk assessment (following Chapter).

Epileptic Seizures and SAH

Epileptic seizures occur in approx. 8% of patients after subarachnoid haemorrhage, 90% of which are observed within the first 24 hours. [11-13] Epileptic seizures occur at a later stage in 3% to 7% of patients. [14, 15] In retrospective studies, intracerebral haematoma, rebleeding, a ruptured aneurysm of the middle cerebral artery, the thickness of the subarachnoid blood clot, an unfavourable neurological status and cerebral infarction have been identified as risk factors for the occurrence of epileptic seizures in the early phase of subarachnoid haemorrhage. [14-18] The significance in terms of the impact on the prognosis of a patient with epileptic seizures in the early phase of subarachnoid haemorrhage is not clear. In some studies, epileptic seizures were not found to influence the outcome. [13, 15, 19] A correlation to a poor clinical outcome was established in a retrospective study, however. [20] Although prophylactic anticonvulsant medication after subarachnoid haemorrhage has not as yet been found to produce a favourable therapeutic outcome, prophylactic antiepileptic

treatment is used widely for preventing the risk of rebleeding from an untreated ruptured aneurysm during an epileptic seizure. This concept is furiously debated, meaning that a general recommendation for prophylactic anticonvulsant treatment cannot be pronounced [21].

Figure 1. According to the modified Fisher scale the CT-Scans of four different patients with subarachnoid hemorrhage (A-D) demonstrate an increasing clot burden at the basal cisterns. A: Grade I hemorrhage with minimal blood at the interpeduncular cistern. B: Also grade I haemorrhage, but significant more CSF-spaces are filled with blood. C: Subarachnoid haemorrhage grade IV with substantial blood in the sylvian fissure on the left. D: CT also reveals intraventricular blood and intraparenchymal hematoma corresponding grade V.

DIAGNOSTIC IMAGING

Once the patient with subarachnoid haemorrhage has received primary clinical care, appropriate diagnostic imaging should be arranged without further delay to detect the actual

cause of the given symptoms. In doing so, it is important not only to establish the diagnosis of subarachnoid haemorrhage in itself, but also to detect a life-threatening situation that could potentially exist due to space-occupying subdural or intracerebral haematoma, decompensated hydrocephalus or severe cerebral swelling.

Computed Tomography

Non-contrast computed tomography is the first examination when SAH is clinically suspected and is at the same time the diagnostic imaging method of choice. Hyperdense blood in the basal cisterns and fissures is a characteristic feature of SAH on cranial CT (CCT). However, the haemorrhage is not necessarily confined to the subarachnoid space, but can also involve the ventricles, subdural space and brain parenchyma, consistent with intracerebral haemorrhage (Figure 1). The sensitivity is affected by the volume of blood, the time since symptom onset, the scanner properties and the experience of the examining radiologist. CT produces false negative results in approx. 2.5% – 7% of aneurysmal SAHs. On the day the haemorrhage occurs, extravasal blood can be detected in more than 95% of patients. [22, 23] As blood can be flushed out of the cerebrospinal cavities relatively quickly, the sensitivity of cranial CT drops to 50% on the seventh day following the haemorrhage [24].

Lumbar Puncture

In a small group of patients with negative cranial CT and transient sudden headache, metabolites of haemoglobin can be identified within the first 12 hours by lumbar puncture and intracranial aneurysm, in fact, in a subsequent angiography. Therefore, a lumbar puncture is certainly indicated in patients with a clinical event and negative cranial CT, even when the cerebrospinal fluid findings are normal in a majority of the examinations. The puncture itself should be performed with great care and ensue within a suitable time frame, no earlier than six hours after the onset of symptoms. This seems to be easier than it is in reality in order to obtain reliable results. The traditional three-glass test is not considered appropriate in this regard [25].

Computed Tomographic Angiography (CTA)

CT angiography has now become more valuable in the first-line work-up of spontaneous SAH than catheter angiography. On the one hand, the sensitivity of CTA in detecting an intracranial aneurysm is the same as that of catheter angiography. [26, 27] In addition, CTA has other apparent advantages that have contributed to this development. These include its less invasive nature compared to DSA, lower costs, reduced time and effort, as well as the simultaneous ability to depict the bony structures at the base of the skull. However, despite the modern scanner technology, the negative predictive value is only 82% to 96% [28, 29], meaning that CTA cannot completely replace DSA even today. It is with aneurysms of less than 3 mm in size that the diagnostic confidence is reduced [30-32].

DSA and Three-Dimensional Rotational Angiography

Angiography of the cerebral arteries is not only intended to detect one or more aneurysms as the underlying cause of spontaneous SAH, but also provides further essential information about the exact configuration of the aneurysm and its adjacent angioarchitecture, which is needed in order to decide on the appropriate treatment option of surgical clipping and endovascular coiling. Even when a cerebral aneurysm was not detected in non-invasive diagnostic testing, DSA led to a change in treatment strategy in 19% to 30% of patients [33].

Angiography is invasive, however. The risk of transient or permanent neurological complications during an angiogram of the cerebral vessels after subarachnoid haemorrhage is 1.8%, [34] and that of intraprocedural rebleeding from the ruptured aneurysm 1%-2% [35, 36].

In approx. 15% of spontaneous subarachnoid haemorrhage cases, primary diagnostic testing including conventional angiography does not detect an aneurysm of the cerebral arteries. Repetition of conventional angiography after 10 to 14 days is mandatory in such a case, since in a substantial number of patients a missed aneurysm can be subsequently detected [37].

MRI

Because of the high diagnostic significance of computed tomography in the acute phase of subarachnoid haemorrhage, the shorter examination times and the simple workflow required for the intensive care patient, the number of MRI studies in the initial diagnostic testing of subarachnoid haemorrhage is very low. Fresh subarachnoid bleeding within the first 12 hours after symptom onset can be detected in FLAIR sequences. [38-40] MRI reaches a sensitivity comparable to that of CT [38, 40].

Figure 2. MRI of a 36-year-old women in the 22th week of pregnancy suffering by acute onset of severe headache and vomiting. In a fresh T2-hyperintensive subarachnoid haemorrhage in the basal cistern can be detected in FLAIR sequences. 3D-MIP reconstructed TOF-MRA (b) shows two saccular aneurysms at the M1- and M2-segment of middle cerebral artery on the left. Diagnosis was confirmed on DSA and aneurysm were successfully occluded by endovascular coiling subsequently.

Table 1. Non-aneurysmatic causes of spontaneous SAH

Cerebrovascular lesions
- Arterial dissection - Arteriovenous malformation (BAVM) - Dural arteriovenous fistula - Intracerebral cavernoma - Sinus vein thrombosis - Cerebral amyloid angiopathy - Moyamoya
Inflammatory vascular lesions
- Wegener's granulomatosis - Polyarteritis nodosa - Churg-Strauss syndrome - Behçet's disease - Other types of vasculitis - Mycotic aneurysms
Spinal vascular lesions
- Saccular aneurysm of the anterior spinal artery - Arteriovenous malformation (SAVM) - Dural arteriovenous fistula - Spinal cavernoma
Medicines
- Cocaine consumption - Overdose of anticoagulants
Other causes
- Sickle cell disease - Coagulopathies - Pituitary apoplexy - Meningeal carcinomatosis - Intracranial tumours

Due to the loss of hyperdensity of blood and signal intensity in CT in the days following SAH, the diagnostic significance of MRI in the detection of subarachnoid blood with FLAIR and T2* sequences increases and becomes better than with CT [41].

In avoiding exposure to radiation, MRI is thus a suitable alternative to CT in patients who during pregnancy experience subarachnoid haemorrhage. (Figure 2) In addition, a supplementary cranial and cervical MRI scan is necessary if in the initial diagnostic testing of spontaneous subarachnoid haemorrhage, including catheter angiography, no source of haemorrhage was detectable and other causes have to be ruled out. (Table 1) In approx. 14% of this patient population, other findings are compiled using MRI which substantially alter the further treatment plan in approx. 6% of patients [42].

PREVENTION OF REBLEEDING

Rebleeding from a ruptured aneurysm after subarachnoid haemorrhage is linked with a mortality of up to 74% [43, 44] and with a significantly poorer functional outcome in surviving patients. A significant factor in the acute phase of the illness is that the risk of

rebleeding is at its highest in the first 12 hours and occurs within the first 24 hours 13.6% to 48.6% of cases. [1, 45-48] In fact, about one third of recurrent haemorrhages occur within the first three hours and about one half within the first six hours. Rebleeding during this early time window also appears to have a more negative impact on the clinical outcome than rebleeding at a later stage. [48] After the first day, the further risk of rebleeding is evenly distributed and is about 2% per day, 40% after one month, [1] and 50% after six months [49].

Numerous factors have an influence on the risk of rebleeding. Poor neurological status on admission, [45, 50] initial loss of consciousness, the size of the aneurysm, [50-52] and hypertension above 160 mm Hg [45, 52] as well as a lengthy period until definitive aneurysm treatment increase the risk of rebleeding. Early treatment of the aneurysm can reduce the risk of rebleeding [53, 54].

Antifibrinolytic treatment with tranexamic acid or epsilon-aminocaproic acid has proven effective in protecting against rebleeding after an aneurysm has ruptured. [55-57] However, because of the increased risk of secondary vasospasm and cerebral ischaemia, the overall clinical outcome is not positively affected, [58, 59] meaning that this treatment has not found a place in clinical practice. Nevertheless, it may be feasible under certain circumstances [60].

ACUTE HYDROCEPHALUS

The occurrence of acute hydrocephalus as a result of subarachnoid haemorrhage is a frequent complication and in an initially awake patient typically causes subsequent gradual deterioration in the level of consciousness. Figures related to frequency vary between 15% and 87%. [60-62] An initial enlargement of the ventricles, especially the temporal horns, is frequently attempted but regresses within the first two days. In fact, in about 50% of patients with acute hydrocephalus the clinical symptoms regressed spontaneously in the first 24 hours without any specific intervention. [63] (Figure 3) Acute hydrocephalus is to be seen as an independent risk factor for a poor clinical outcome [64, 65].

Figure 3. CT (a-c) demonstrates acute hydrocephalus of a 42-year-old individual following subarchnoid hemorrhage. However the were no significant clinical symptoms related to hydrocephalus and initial enlargement of the ventricles regresses within the first two days without any specific intervention.

Pathophysiologically, there are two mechanisms behind the development of acute hydrocephalus. Firstly, the circulation of cerebrospinal fluid is displaced into the ventricles and basal cisterns by intraventricular or subarachnoid blood, [66] and secondly, reabsorption of the cerebrospinal fluid at the level of the arachnoid granulations is decreased. In contrast, the later chronic hydrocephalus is the result of secondary, reactive fibrosis and adhesion of the leptomeninges, which restrict the CSF circulation. [67-70] The hypothesis that subarachnoid haemorrhage increases the production of cerebrospinal fluid is furiously debated in the literature and to date has not been proven with any certainty [71-74].

Risk factors for acute hydrocephalus from subarachnoid haemorrhage are intraventricular bleeding, a substantial volume of blood in the subarachnoid space, increasing loss of consciousness, increased patient age, and an aneurysm located in the posterior circulation [75, 76].

Proven and symptomatic hydrocephalus is treated with an external ventricular drain and more rarely in clinical practice with lumbar drainage or a series of lumbar punctures. After an external ventricular drain has been inserted, an improvement in the patient's neurological condition is generally seen due to the reduction in intracranial pressure. [77-79] A recently published prospective cohort study came to the conclusion that use of an external drain must be regarded as an independent risk factor for rebleeding. [80] In this context, preliminary retrospective studies also identified an increased risk of rebleeding. [79, 81] However, there are also studies that did not report an increased risk of rebleeding after placement of an external drain for treatment of hydrocephalus following subarachnoid haemorrhage [82, 83].

Chapter 68

ENDOVASCULAR TREATMENT OF ANEURYSMS. PRE-, PERI- AND POST- INTERVENTIONAL MANAGEMENT

G. Friedrich Götz

Medical School Hanover, Hanvover, Germany

ABSTRACT

Endovascular treatment is a minimally invasive procedure for occluding cerebral aneurysms. The number of aneurysms undergoing endovascular treatment in different hospitals and countries is astonishingly varied. The ISAT study has demonstrated that interventional treatment offers an advantage over surgical treatment in the management of ruptured intracranial cerebral aneurysms. In the treatment of unruptured intracranial aneurysms, surgical and endovascular procedures are equally effective, but in incidental middle cerebral artery bifurcation aneurysms clipping is superior. Continuing advances in interventional tools has resulted not only in a reduction of the complication rate, but also an expansion of the therapeutic spectrum to include complex aneurysms.

Keywords: subarachnoid haemorrhage (SAH), coils, balloon remodelling, intracranial stent, stent-assisted coiling, flow diverter, antiplatelet treatment, MR angiography, follow-up, ISAT, barrow institute study

Endovascular treatment is a minimally invasive procedure for occluding cerebral aneurysms, which can be space-occupying, symptomatic or incidental. This interventional procedure is the treatment of choice for aneurysms which in neurosurgical terms are difficult to reach – especially those at the basilar tip. The prospective, randomised ISAT study [1] has demonstrated that interventional treatment offers an advantage over surgical treatment in the management of ruptured intracranial aneurysms. Endovascular treatment leads more rarely to a slight drop in the post-therapeutic GCS and to post-therapeutic epilepsy [2]. In the treatment of unruptured intracranial aneurysms, surgical and endovascular procedures are equally effective, but in incidental MCA (middle cerebral artery) bifurcation aneurysms clipping is

superior [3, 4]. The number of aneurysms undergoing endovascular treatment in different hospitals and countries is astonishingly varied, however. Continuing advances in interventional tools has resulted not only in a reduction of the complication rate, but also an expansion of the therapeutic spectrum to include complex aneurysms. Endovascular treatment comprises a variety of different therapeutic approaches such as coil embolisation of the aneurysmal sac or other method of embolisation, flow modulation in the parent artery, as well as implantation of devices for bridging the aneurysm neck. Therapy can be customised by using varied combinations of these technical aids. Thanks to special interventional tools, continuing miniaturisation and optimised biocompatibility, and increasing experience worldwide, the number of aneurysms that cannot be treated interventionally has been minimised.

Proximal vessel occlusion and diversion of the blood flow in aneurysms of the intracranial vertebral artery and the cavernous internal carotid artery today represent an established, yet seldom employed therapeutic concept. The procedure can induce thrombosis of the aneurysm, and prevent both an increase in size and rupture. Interventional vascular occlusion with balloons, coils or, more effectively, so-called vascular plaques, is superior to surgical vessel ligation, since during angiography collateral cerebral perfusion can be evaluated.

Figure 1. Endovascular treatment with coils: . 58 male with Subarachnoid Haemorrhage Hunt & Hess grade 2. a) 3D digital subtraction angiography, b + c) subtracted and un-subtracted frontal projection after embolisation with two coils.

Conventional endovascular treatment entails filling the lumen with coils to occlude the aneurysm. Berry-shaped aneurysms with a narrow neck (smaller than 4 mm) and favourable dome-to-neck ratio (larger than 1.4 mm), respectively, can be treated with coils only and without having to permanently modulate the coagulation. After carefully probing the aneurysm with a microcatheter the three-dimensional expanding coils are inserted in decreasing order of diameter. Small and short coils can be used to ensure that they fit snugly against the parent vessel. The aim is to pack the aneurysm as densely as possible with coils, reduce perfusion of the aneurysm to zero and thus induce thrombosis and subsequent fibrosis. The rate of complications from coil embolisation is less than 10%; this includes

thromboembolic and haemorrhagic complications at less than 5% and 2%, respectively. The permanent occlusion of an aneurysm depends not only on the density with which the implanted coils are packed (up to 40 % of the aneurysm lumen are filled with coils), but also on the flow properties in the parent vessel and stability of the wall. The occlusion rate is stratified in accordance with the Raymond classification into complete (class 1), residual perfusion of the aneurysm neck (class 2, equivalent to 90%-95%) and incomplete (class 3, marked remnant/reperfusion >90%) [5] (Figure 1).

The technique in use the longest for improving the treatment options for wide-necked intracranial aneurysms is remodelling [6]. It involves brief inflation of a balloon in the parent artery so as to stabilise the coils in the aneurysm. To use a balloon catheter and microcatheter simultaneously, a wide-bore or second distal access and/or guide catheter is required. Prior to balloon insufflation, a bolus dose of heparin is usually injected intravenously. This method, which requires considerable technical dexterity, permits dense packing of the coils and, as a result, safe and stable occlusion of broad-based aneurysms. Another advantage of this technique is that it provides protection for the efferent blood vessels in close proximity to the base of the aneurysm, especially at the MCA bifurcation, the A1/A2 junction, the posterior communicating artery and the basilar tip, and permits action to be taken immediately in response to a ruptured vessel (Figure 2).

Figure 2. Balloon remodelling: 44 female with an aneurysm of the basilar tip and a history of Subarachnoid Haemorrhage Hunt & Hess Score 4 and of coil embolisation. Modified Rankin Scale 0. a) 3D DSA b) Working projection with balloon catheter (Eclipse 6 x 9, Balt®) at the aneurysm fundus (the markers indicate the length of the balloon) and microcatheter tip at the base of the aneurysm. c + d) unsubtracted and subtracted DSA. Embolisation of the basal reperfusion with a coil using balloon inflation for scaffolding.

Permanent implants in the parent artery generally necessitate modulation of coagulation over a prolonged period. This also applies to the latest generation of intracranial stents, the thrombogenicity of which is much lower than with older models. Hence, stent-protected coil embolisation as a treatment for ruptured aneurysms can only be recommended to a limited extent. Wherever possible, coils are used exclusively in the treatment of an acute aneurysm rupture.

The premedication used most commonly prior to permanent implantation of a device in the cerebral vasculature entails a daily dose of 100-300 mg aspirin and 75 mg clopidogrel for a minimum of five days, or a loading dose of 450 mg clopidogrel and 100 mg aspirin the evening beforehand. To monitor the regular intake and the efficacy of the medication, specific coagulation analysis is recommended immediately before the intervention. If the standard

medication does not satisfactorily modulate the coagulation, either an increased dose or alternative drug (e.g., ticagrelor) can be used.

The development of flexible intracranial stents, which are available in an open-cell or closed-cell design, and are interwoven or laser-cut, has expanded the endovascular possibilities for treating wide-necked, complex aneurysms. The stent mesh not only prevents the coils placed into the aneurysm from herniation into the parent artery, but also positively alters the flow properties at the neck of the aneurysm. This should help to reduce the number of aneurysms incompletely embolised at the base and, in turn, the frequency of recurrence. This theoretic advantage is certainly consistent with the results reported in numerous case studies, but has not yet been confirmed by a randomised prospective trial.

Elective stent-assisted coil embolisation necessitates modulation of the coagulation as described above. If emergency stent implantation is required to correct prolapsed coil loops or to treat peri-interventional vascular dissection, 500 mg of intravenous aspirin and an intravenously effective platelet aggregation inhibitor as a bolus and subsequent infusion should be administered during the procedure. Long-term medication should be initiated with a loading dose of clopidogrel (e.g., 450 mg via gastric tube) at the periprocedural stage.

Figure 3. Stent assisted coiling: 66 male who presented with an incidental basilar tip aneurysm and vertebrobasilar arteriosclerotic stenosis. a) Stent implantation (LVIS junior 3.5 x 18 Microvention®) via the left posterior communicating artery into the right posterior cerebral artery b) Post coil embolization c) Treatment outcome after 6 months (subtracted DSA after right vertebral artery injection).

Coiling with stent assistance can be performed in one or two stages. To accurately deploy the stent, a stable access route is required – ideally consisting of a guide, distal coaxial and microcatheter. Using the jailing technique, the microcatheter placed in the aneurysm is fixed with the subsequently deployed stent and then carefully removed after coiling is complete. As with remodelling, this approach requires two microcatheters to be inserted simultaneously in the parent vessel. Alternatively, the stent can be implanted first and coiling performed six weeks later at the earliest. With this method, it is necessary to probe the aneurysm through the tines of the stent. This can be done even with small and flat aneurysms once the stent has stabilised. Sequential stent implantation and coiling during an intervention is less advisable, since probing the aneurysm can cause the stent to become misaligned if it has not yet stabilised (Figure 3).

Wide-necked aneurysms located in the carotid T, the MCA bifurcation or basilar tip have an unfavorable haemodynamic, the so called water hammer effect [7]. The recanalisation rate after coil embolisation, generally known to be high in these aneurysms, is induced by coil compaction and progressive aneurysmal growth. Reconstruction of the base of the aneurysm

and preservation of the efferent arteries pose a particular challenge. Special techniques and materials are required to treat such aneurysms.

The base of the aneurysm can be reconstructed by inserting two microstents to form an X or Y shape. The resulting haemodynamic effects vary depending on the design of the stent and implant geometry [7]. The stents can be implanted in two stages by probing the mesh once the first stent has stabilised, or in one procedure. Different technical variations for vascular reconstruction have been described [8]. The microcatheter for coil embolisation must either be navigated through the struts of the stent into the aneurysm, or be placed in the aneurysm using the jailing technique prior to deployment of the stent. Protection of the efferent arteries allows dense coil packing, which is necessary for preventing recanalization (Figure 4).

Figure 4. Y stenting: 46 female presenting with a wide-necked, incidental basilar tip aneurysm and a history of familial subarachnoid haemorrhage. a) frontal projection of an angiogram. Stent implantation firstly from the right, secondly on the left posterior cerebral artery to the basilar artery (Solitaire® 4 x 20), b) Unsubtracted DSA with Y- stenting in situ and the first coil inside the aneurysm. c) Subtracted DSA after embolisation with two coils.

Intra- and extra-aneurysmal placement of a stent and subsequent coil embolisation is referred to as the waffle-cone technique [9, 10]. The expandable end of the self-expanding microstent is designed for reconstructing and modelling the aneurysm fundus and stabilising the coil.

Figure 5. Waffle cone technique: 28 male with a wide-necked basilar tip aneurysm. Implantation of a pCONus® device and embolisation of the aneurysm with four coils. a) subtracted angiogram, working position. b) unsubtracted projection after expansion of the pCONus® 4-25-5 from the neck of the aneurysm to the basilar artery. c) unsubtracted projection with a second microcatheter placed inside the aneurysm d) subtracted angiogram after implantation of four coils, prior to detachment of pCONus.

A stent-like device with a distal portion that unfolds like a flower is suitable in particular for treating wide-necked bifurcation aneurysms [11, 12]. The distal end, which opens out into a disc shape, is used to secure the aneurysm fundus, whilst the proximal end ensures stabilisation in the parent artery. Stable anchorage facilitates probing of the aneurysm and coiling. Compared to X and Y stenting, the waffle-cone technique using the described device is easier to perform and is regularly done within one treatment procedure (Figure 5).

Flow diverters are flexible, self-expanding stent-like devices with a more dense wire mesh. They modulate the blood flow in the parent vessel, reduce inflow of blood into the aneurysm. Consequently they, or when Combined with loosely packed coils flow diverters promote occlusion of the aneurysm. The high mesh density of flow diverters results in low porosity of these implants. Porosity is a measure of permeability to liquid, and describes the ratio of the free surface not covered by struts to the total surface. A flow diverter is most effective if it is densely woven with as little material as possible. The goal is achieved technologically if the product offers low permeability combined with high flexibility and good wall apposition.

Compared to intracranial microstents, the denser wire mesh of flow diverters inevitably results in relatively high thrombogenicity. It is essential to adequately modulate the coagulation at the time of implantation. Following the intervention, treatment with aspirin and Plavix should continue for a minimum of 3-6 months. Since late thromboembolic complications have been reported [13, 14], consideration should be given to modulating the coagulation for an even longer period in individual cases.

Figure 6. Arteriosclerotic fusiform vertebrobasilar aneurysm: 60 female with progressive brain stem symptoms. a) Angiogramm after injection of the right vertebral artery. b) 3D digital subtraction angiography. The terminal segments of both vertebral arteries and the basilar artery are incorporated in the aneurysm sac. c + d) Subtracted and unsubtracted DSA after implantation of a stent (Leo® 4.5 x 75) and a flow diverter (Silk® 5.5 x 50).

Flow diverters are suitable for the management of wide-necked and dysplastic aneurysms. They offer promise in the treatment of dissecting aneurysms and blood blister-like aneurysms that are extremely difficult to manage [15, 16]. Despite the initial euphoria, clinically viable therapeutic outcomes with fusiform aneurysms can only be expected if such treatment is strictly indicated. Large vertebrobasilar, fusiform aneurysms are a particular therapeutic challenge given the numerous efferent perforators, as well as the lack of mural stability and parietal thrombi. Vascular reconstruction with a stable, self-expanding stent and additional implantation of a flow diverter may be necessary in the treatment of extremely wide, fusiform aneurysms. Although causal therapy would appear to be possible with such a device, peri-

interventional mortality is significant and good long-term outcome has been achieved rarely (Figure 6).

A hazardous scenario arises if an aneurysm ruptures after implantation of a flow diverter [17]. This can possibly be caused by a small amount of blood continuing to flow into the aneurysm but the outflow being blocked, thus increasing the intra-aneurysmal pressure. This potential complication can probably be ameliorated by partially coiling the aneurysm. The rational use of flow diverters is hindered by the fact that the pathophysiological effects are not fully understood, combined with a lack of randomised studies [14, 18] as opposed to numerous case studies and small retrospective series.

A cork-like implant made of interwoven nitinol fibres that unfolds inside the aneurysm is also suitable for treating wide-necked aneurysms. The wire, ball-like device is selected in a suitable size based on the maximum transverse diameter of the aneurysm. It can be modelled to fit the wall to the parent artery perfectly prior to electrolytic detachment. Perfusion of the aneurysm often ceases immediately after the implant has unfolded. An advantage with this technique is the possibility to use it in the event of acute rupture of an aneurysm, since modulation of the coagulation is not essential [19, 20] (Figure 7).

Figure 7. WEB® (woven endobridge): in superior cerebellar aneurysms. 59 female, history of sentinel bleeding and a wide-necked basilar artery aneurysm between the origin of the superior cerebellar and posterior cerebral arteries on the left. a) 3D digital subtraction angiography. b) DSA after implantation of a WEB® SL 2-8-S device. Immediate cessation of aneurysm perfusion. c) Angiogram after electrolytic detachment of the device and complete occlusion of the aneurysm.

POST-INTERVENTIONAL MEASURES

If coiling has been completed successfully without complications, post-interventional pharmacological modulation of the coagulation is not necessary. If individual tines prolapse into the carrier vessel, intravenous or subcutaneous heparin can be prescribed for five days; aspirin is likely to be equally effective.

Aspirin (100-300 mg) and clopidogrel (75 mg) are essential for modulating the coagulation when implanting stents and flow diverters. When prescribing dual antiplatelet therapy, additional gastric protection is usually recommended. After implanting intracranial

stents, drug therapy is switched no sooner than eight weeks later to long-term aspirin and is continued for a minimum of one year.

Dual antiplatelet therapy should last longer if a flow diverter has been implanted. Reports of late thromboembolic complications [12, 13] call the six-month limitation of intensive anticoagulation into doubt. It is therefore advisable to consider the benefits and risks in each individual case. Most authors recommend lifelong continuation of aspirin after dual antiplatelet therapy once a flow diverter has been implanted. The thrombogenicity of the implants can be expected to decrease in future thanks to improved surface technology.

MRI is used preferentially in the follow-up of aneurysms after coil embolisation [19-23]. High-resolution, thin-section 3D TOF sequences are used by most practitioners. Analysis must not be restricted to MIP reformations, but must account for the individual axial images.

The coil-filled aneurysm is displayed on 3D TOF MRA as a compact, attenuated signal. The contrast to the flow signal in the adjacent artery is high. Segments of the aneurysm that are still perfused and not excluded from the circulation exhibit a bright signal and can be identified precisely from the 3D TOF images. Visual assessment of the treatment outcome is most reliable if it is done by two examiners using a three-part scale [24] (Figure 8).

Figure 8. MRA after endovascular treatment: (a+b) 3D TOF MRA (3 Tesla) thick-slice MIP reformations complete exclusion with a homogenous signal void inside a basilar tip aneurysm post coiling. c + d) 3D TOF MRA (3 Tesla). Axial source images of a 72 male show an area of recurrence at the neck of an ophthalmic ACI aneurysm on the right.

Contrast-enhanced head and neck angiography is less often used for post-interventional assessment of aneurysms. In the current literature, 3D TOF MR angiography is reported to offer greater sensitivity with rather than without contrast enhancement [21, 23]. The use of a contrast agent does not ensure that a distinction can be made between flow and a contrast-enhanced thrombus, however. In the authors' opinion the minimal gain in sensitivity is therefore accompanied by a decrease in specificity. Infectious complications or an inflammation of the aneurysm wall are absolute indications for the application of contrast agents.

Although all intracranial stents and flow diverters are MR-compatible, image distortion of varying degrees does occur with the individual implants. The implants of a number of manufacturers cause a large void in the signal [21] and hamper the assessment of the carrier vessel and aneurysm region. Others permit identification of the parent vessel, but might mistake the artefact of the device for stenosis. Artifacts also depend on the field strength of the used MRI system and can be so misleading that conventional DSA will be required in order to elucidate the situation. Despite the high material density, unexpectedly small artifacts occur with intrasaccular flow disrupters on MRI, meaning that in principle non-invasive

follow-up is possible. For the woven endobridge intra-arterial catheter angiography is recommended three months after implantation, since early reperfusion of aneurysms was not detected by MRI in all cases [20].

Figure 9. Recurrence after therapy: a+ b) 49 female with a history of SAH I and embolisation of a basilar tip aneurysm with coils . Recurrent SAH and regrowth of the aneurysm 9 years later. Digital subtraction angiography with frontal and lateral projection c + d) 52 male presents with headaches and aneurysm recurrence. History of SAH and clipping in 1992 for basilar tip aneurysm, no follow-up since.; Unsubtracted and subtracted DSA, frontal and lateral views, prior to stent assisted coiling.

The modified Raymond classification is often also applied in the evaluation of the treatment outcome after using other devices than coils. It can take up to six months to completely occlude a wide-necked aneurysm with a flow diverter. Therefore, the last angiogram taken on the day of the procedure to assess the therapeutic outcome will not be conclusive, since a further reduction as well as an increase in the perfusion of the aneurysm can result [15]. MRA usually is scheduled at 6-12 months after endovascular aneurysm treatment. The timing should be scheduled individually, however, depending on the course of the intervention and the implants used. If MRA follow-up reveals a change over the final angiogram taken at intervention, it is advisable to perform intraarterial DSA for confirmation

and to weigh up therapeutic consequences. In all cases in which stable occlusion of the aneurysm is achieved, cerebral catheter angiography is not necessary. Depending on the type of materials implanted, MRA may not be sufficient to reliably evaluate the therapeutic outcome.

The recanalisation rate after endovascular coiling is reported at up to 40% and is much higher than after clipping [2-4, 25, 26]. Remarkably, this treatment outcome evidently correlates only vaguely with the number of recurrent bleeds [26, 27]. Complete occlusion of an aneurysm with coils might be not necessary for cure and continuing protection against rebleeding. The decision whether reintervention for incompletely occluded aneurysms is indicated should be made on a personalized basis. As long as valid data on the long-term outcome of endovascular aneurysm treatment remain sparse [26, 27], follow-up examinations are still mandatory. Recommendations for follow-up also account for the occurrence of de novo aneurysms, which are reported at a rate of up to 1% per year.

Recurrence can occur after both endovascular and surgical treatment due to aneurysmal growth associated with arteriopathy (Figure 9). Recanalisation and recurrent SAH following endovascular treatment are observed more often in smokers than in non-smokers.

Chapter 69

ANEURYSMS: SURGICAL THERAPY

Ralph König

Department of Neurosurgery, University of Ulm,
Ludwig-Heilmeyer-Straße 2, Günzburg, Germany

ABSTRACT

The following chapter addresses several peculiarities with regard to surgery for ruptured intracranial aneurysms. Furthermore the chapter tries to give an insight in newer developments of neurovascular, especially aneurysm surgery: tailored approaches, retractorless neurosurgery, endoscopic and endoscope assisted aneurysm surgery. Furthermore it provides an overview of intraoperative imaging and electrophysiology in aneurysm surgery.

Keywords: aneurysm surgery, retractorless neurosurgery, tailored approaches, intraoperative angiography, intraoperative electrophysiology

INTRODUCTION

“Endovascular therapy has changed the practice of vascular neurosurgery forever” [1]. Albeit the subject of best treatment for ruptured aneurysms of the anterior circulation remains controversial [2-6] there is accumulating evidence that patients undergoing surgical clipping after acute subarachnoid hemorrhage (aSAH) demonstrate substantial postoperative decline of their clinical condition [7]. More precisely, Ayling [8], in a post hoc analysis of perioperative complications from the CONCIOUS-1 Study demonstrated a greater perioperative decline in GCS after clipping compared to coiling. Additionally patients clipped for ruptured aneurysms seem to have higher rates of delayed ischemic deficits (DCI) compared to those treated endovascularly [9, 10].

As a consequence of those data, particularly since the International Subarachnoid Hemorrhage Trial (ISAT) [11] the number of ruptured aneurysms treated endovascularly increased steadily. A paradigm shift in acute management of patients with ruptured

aneurysms occurred in many neurovascular centers around the world [12]. In spite of this general development one should not lose sight of the fact that the most appropriate treatment for an individual patient might be different in various treatment centers, as the level of endovascular or surgical experience varies. Furthermore in the presence of SAH endovascular procedures that require dual antiplatelet therapy (stent remodeling, flow diversion) should be avoided, as this has important ramifications for necessary subsequent surgical procedures (CSF-diversion, central venous lines, ICP measurement, tracheotomy).

Regardless of any further developments in endovascular therapy there will be ruptured aneurysms that require surgical treatment. Therefore aneurysm clipping will retain importance in the future. Also, more or less in obscurity and silent aneurysm surgery refined in the recent years:

- Application and adaption of tailored minimally invasive skull base approaches
- Retractorless surgery [13, 14]
- Endoscopic and endoscope-assisted techniques [15, 16]
- Intraoperative neuromonitoring [17, 18]
- Intraoperative imaging and visualization techniques [19] [20-22]

CLIPPING OF RUPTURED ANEURYSMS

Clipping of ruptured aneurysms is the other side of the same coin. Albeit the objective is the same, complete clipping of the aneurysm without a remnant and compromise of parent vessels, surgery for ruptured aneurysms has various specific characteristics compared to unruptured ones.

- First timing of treatment: Based on the results of the cooperative study the optimum time for definitive aneurysm treatment shifted from late (>7 days after aSAH) to early (<3 days after aSAH) (Kassell: 1990di; 23). Today, to further reduce the risk of recurrent haemorrhage from ruptured aneurysms a policy of urgent treatment within the first 24 hours after bleeding is pursued. But this might not be the end of the story as there seems to be some evidence for emergency treatment of ruptured aneurysms [24].
- Second, the “angry, red, swollen brain”: In the presence of SAH the brain is vulnerable and swollen, due to brain edema, acute hydrocephalus and potential intracerebral haemorrhage. The subarachnoid cisterns are filled up with clotted blood and anatomy might be distorted from space-occupying intracerebral hematoma. Therefore to gain space and to get access to the relevant pathology is hampered, particularly as premature intraoperative rupture threatens to complicate the procedure. Generous indication for CSF diversion, either by ventricular or lumbar drainage helps to relax the brain, as suction of CSF from the basal cisterns is made difficult by clotted blood. Further osmotic therapy administered by the anaesthetist may help to create a slack brain. Temporary mild hyperventilation may additionally help if the aforementioned measures fail [25].

- Third, temporary clipping: temporary clipping is used frequently especially during surgery for ruptured aneurysms. On the one hand it is used to deal with intraoperative rupture, which occurs between 7 and 35%, depending on various aneurysm and surgeon specific factors (Batjer: 1986wq; Fridriksson: 2002if; 26). On the other it is a helpful adjunct in the final dissection of the aneurysm dome and clip application, especially in larger aneurysms. Griessenauer, in the so far largest study about the effect of temporary clipping in ruptured aneurysms concluded, that limited temporary clipping did not affect clinical outcome in patients with aSAH [27]. Perfect interaction and communication between the anaesthesiological and surgical team helps to reduce potential harmful effects of temporary artery occlusion.
- Fourth, posthaemorrhagic hydrocephalus: surgery with or without opening of the lamina terminalis during the procedure does not have any positive effect on shunt dependency after aSAH, but on the contrary seem to result in an elevated risk for shunt dependency compared to endovascular therapy [28]. Apart from that aneurysm location, especially ruptured anterior cerebral artery ACA aneurysms, and the amount of blood are predictors for persistent posthaemorrhagic hydrocephalus.

MINIMALLY INVASIVE OR TAILORED APPROACHES TO ANEURYSMS

In public the term “minimal invasive surgery” unfortunately is connoted in particular with small skin incisions. This does not necessarily imply, that a minimal invasive procedure is minimal invasive in handling with crucial structures e.g., the brain. In this respect minimal invasive surgery may turn out to be rather invasive and harmful. Therefore the term keyhole approach (or tailored approach), as coined by Axel Perneczky [29] seems to be a more appropriate designation for the concept of moving away from standard approaches (“one size fits all”), but instead come down to small approaches, which take into account the individual anatomy and pathology of each case. e.g., a tailored approach for a ruptured ACM aneurysm with associated space occupying temporal intracerebral haemorrhage might not be a osteoplastic supraorbital craniotomy, but a decompressive craniectomy.

A crucial prerequisite for tailored approaches is excellent preoperative planning based on multimodal (e.g., MRI, CT, DSA) neuroradiological cross-sectional and 3D imaging. In order to realise multimodality planning for complex neurovascular procedures computerized planning is helpful. Meanwhile even coregistration of projectional DSA data with 3D datasets allows for 4-D planning, taking into account the fourth dimension: time (Smartbrush Angio, Brainlab AG, Feldkirchen). Based on 3-D imaging development of surgical simulation tools using virtual or physical models proceed [30]. Concerning to this especially 3D printing techniques appear as a promising tool in the future [31-33].

RETRACTORLESS SURGERY

By now the potentially harmful effects of static brain retraction have been well described and the underlying cellular and molecular mechanisms of injury were unveiled [34-37]. In their publication entitled “The quiet revolution: retractorless surgery for complex vascular

and skull base lesions”, Spetzler and Sanai [13] described a technique to overcome fixed retraction by dynamic retraction with surgical instruments. Especially the sucker and suction hand play a critical role as a mobile, “roving retractor” [1]. The sucker complements the dissecting instrument providing e.g., countertraction while cutting arachnoid bands with microscissors. Along with an extensive arachnoidal dissection, careful patient positioning allowing for gravity retraction of the brain this technique allows for a limited retractor-induced tissue injury even in complex vascular and skull base lesions.

To put it in the right light: limited use of retractors, e.g., in the final stage of aneurysm clipping after careful dissection is not a problem. But use of fixed retraction should be reduced to the minimum.

INTRAOPERATIVE IMAGING AND VISUALIZATION

The idea of intraoperative angiography (IOA) goes back to almost 50 years now [38, 39]. The rationale is based on the studies of Drake [40], dealing with the “...late consequences of incomplete surgical treatment of cerebral aneurysms”. The potential benefit is obvious: prompt and correctable detection of inadvertent aneurysm residuals and parent vessel or branch occlusion respectively.

In the so far largest contemporary study of IOA dealing with IOA performed during surgical treatment of 976 aneurysms Chalouhi et al. [19] described a clip revision rate of 8.2%. Reasons for clip readjustment were residual aneurysm in 54, 7%, parent vessel occlusion in 42.9% and a combination of both in 2.4% of cases.

Albeit the benefits of IOA seem to be clear the critique never silenced: besides safety concerns, accuracy, duration and costs appeared as main arguments against routine use of IOA in aneurysm surgery. Further the development of intraoperative microscope-based Indocyanine Green Angiography (ICG) seemed to make IOA superfluous.

- Safety concerns: Complications, especially permanent stroke rate due to IOA reported in the literature exceed by far that of routine cerebral angiography [41]. The prevailing mechanism thereby is vessel injury (dissection) on catheter access caused by distorted vessel anatomy due to patient positioning and thromboembolic events [42-44]. However, most of those publications date back 20 years. Further development and distribution of imaging technology e.g., enable intelligent catheter navigation from groin to neck, therefore reducing the risk of vessel injury. In their review of 1093 consecutive cases, Chalouhi et al. [19] for instance report about 0.99% of transient or minor complications, none resulting in permanent morbidity.
- Diagnostic accuracy: Diagnostic accuracy of IOA has always been one important criticism as the rate of false negative findings range up to 8.7%. Similar to complications ongoing technical development and integration of modern flat panel diagnostic imaging devices into the operation theatre with the possibility of 3D-rotational angiography helped to overcome that issue. Apart from very few exceptions image quality of IOA come about standard diagnostic angiography [45, 46].

- Duration and costs: in health care systems always under pressure to control costs IOA is not economically advantageous, as it extends operation time by at least 15 to 20 minutes. But, in a more comprehensive view calculating the incremental cost-utility ratio for routine IOA Kallmes et al. [47] proved IOA to be cost-effective in a manner consistent with low morbidity as it helps prevent clinically relevant cerebral infarctions.
- IOA in the era of ICG: development of microscope-based ICG was an important landmark in neurovascular surgery [20]. ICG enables for simple, easy intraoperative control of vessel patency and aneurysm obliteration. However, thorough evaluation of ICG in aneurysm surgery yielded some discordance between ICG and intra- or postoperative control angiograms. Reasons include the “field of view” problem of ICG and its weakness for low-flow detection (e.g., residual inflow to an aneurysm) [48-50].

Devoid of intraoperative imaging modalities yielding comparable diagnostic accuracy, nowadays associated with a low complication rate IOA still remains a valuable tool in neurovascular surgery, especially in aneurysm surgery. Klopfenstein [51], in a comparison of routine and selective use of IOA during aneurysm surgery concluded, that “given the frequency of significant disease that remains undetected if IOA is used on a selective basis and the low complication rate associated with the procedure, the use of IOA should be considered in the majority of aneurysm cases”. To put it into the right light: we are far away of considering IOA as a standard in aneurysm surgery. But it proves to be very helpful, especially in large aneurysms, tailored approaches and aneurysms previously treated endovascularly.

INTRAOPERATIVE ELECTROPHYSIOLOGY

In a series of 50 unruptured large and giant aneurysms Takebayashi [52] evaluated the utility of MEP monitoring (direct cortical stimulation) with a focus on the correlation of MEP changes during surgery and postoperative motor function. The study demonstrated a good correlation of MEP recordings and postoperative motor outcome: Preserved MEPs during surgery were always correlated with good motor outcome regardless of duration of temporary vessel occlusion. On the other hand permanent loss of MEPs during the surgical course was always followed by severe and permanent motor deficits.

Unfortunately the validity of intraoperative monitoring during vascular neurosurgical procedures is considered rather low compared to brain tumor surgery. Wicks et al. [53] for example, in a recent consecutive series of 691 patients determining accuracy of SSEP changes in predicting postoperative stroke rate reported positive and negative predictive values of 30% and 94% respectively. In Szelenyi's series using MEP recordings [54, 55] a relatively high rate of false negative results with motor evoked potentials (MEP) (postoperative motor deficits without intraoperative MEP changes) occurred. These findings were especially ascribed to delayed neurological deficits caused by lacunar infarction from perforating arteries. Hence development of lacunar infarcts may take longer than 12 hours [56] these could not be detected with intraoperative recordings.

Though intraoperative neuromonitoring during cerebral aneurysm surgery is not standard today, especially MEP recordings seem to be a rather robust prognostic factor for postoperative motor outcome. SEP's and MEP's may give real-time feedback regarding the individual ischemic tolerance e.g., during temporary clipping. Although not always possible, alterations in monitoring may initiate an alternative surgical strategy (e.g., clip alteration, additional bypass) and therefore have the potential to improve operative safety [54].

Chapter 70

DECOMPRESSIVE CRANIECTOMY AND ANEURYSMAL SUBARACHNOID HAEMORRHAGE

Stefan Röhrer

Department of Neurosurgery, University of Ulm, Ulm, Germany

ABSTRACT

Cerebral vasospasm is a redoubtable complication of subarachnoid hemorrhage. Due to this cerebral infarction may be the consequence. At worst, a space-occupying infarct can develop and threaten patients life additionally which will necessitate decompressive craniectomy.

It is known that decompressive craniectomy can reduce the increased intracranial pressure, but this is often fraught with severe complications.

Keywords: cerebral vasospasm, subarachnoid hemorrhage, decompressive hemicraniectomy, cerebral oedema

PATHOPHYSIOLOGY OF CEREBRAL OEDEMA

Cerebral oedemas are categorised as being either cytotoxic or vasogenic. Pathophysiologically, cytotoxic cerebral oedema develops as a result of swollen glial cells, as well as disruption to the membranous ion pump (sodium-potassium pump) and intracellular autoregulation. The result is an enlargement of the intracellular space of the brain owing to an influx of sodium into the cells, with water and chloride ions being drawn into the intracellular environment. This type of cerebral oedema mostly occurs with intracerebral bleeding, and cerebral infarctions respectively. The worst possible consequence of the cerebral vasospasms that develop due to a ruptured cerebral aneurysm is cerebral hypoperfusion with consecutive cerebral infarctions. Such infarctions can lead to cytotoxic cerebral oedema, which in turn can result in life-threatening swelling of the brain. Conversely, vasogenic cerebral oedema develops from an impairment of the blood-brain barrier, as well as from increased permeability of the capillary vessels, which can cause the increased influx of fluid into the

interstitium and, in turn, to an enlargement of the extracellular space. This can be caused by traumatic brain injury, abscesses, or brain tumours.

INDICATION FOR DECOMPRESSIVE HEMICRANIECTOMY

In case of traumatic brain injury, decompressive hemicraniectomy is indicated in the event of space-occupying haemorrhage, and space-occupying cerebral oedema with a midline shift on CCT imaging of >5 mm respectively. It is indicated moreover for treating intracranial pressure that is increased to more than 25 mm Hg for 30 minutes and resistant to therapy, as well as cerebral perfusion pressure that is decreased to <50-60 mm Hg at the same time as rising intracranial pressure values.

In case of cerebral infarctions, decompressive craniectomy is indicated due to the development of a mass from secondary swelling of the infarcted cerebral tissue consistent with cytotoxic cerebral oedema. The positive clinical aspects were demonstrated by the DESTINY study.

Cerebral vasospasms with cerebral perfusion deficit can be a secondary consequence of aneurysmal subarachnoid haemorrhage. Cerebral infarctions are a tertiary complication here; at worst, a space-occupying infarct can develop which, depending on the size and the space consumed, will necessitate decompressive craniectomy.

It is known that decompressive craniectomy can reduce the increased intracranial pressure following traumatic brain injury [1] as well as after malignant middle cerebral artery infarctions [2, 3]. Cerebral oedema can accompany the initial bleed in the event of aneurysmal subarachnoid haemorrhage, but can also develop later as a result of cerebral vasospasms and consecutive infarctions. Irrespective of the point at which cerebral oedema occurs, it is known to worsen the outcome of the patient after subarachnoid haemorrhage [4, 5]. Treatment of this life-threatening form of oedema is essential, though this is often also fraught with severe complications such as infections, axonal injury or hygromas. Given that the functional outcome is unclear, especially with severe subarachnoid haemorrhage (WFNS IV-V) accompanied by extremely high intracranial pressure, aggressive therapy in the form of decompressive craniectomy is a topic of hot debate. Between 1999 and 2008, Güresir et al. studied a total of 939 patients with aneurysmal subarachnoid haemorrhage. Decompressive craniectomy was performed in 79 of these patients. The study concluded that decompressive craniectomy is an effective method of treatment for patients with increased intracranial pressure. It was also demonstrated that surgery to treat the pressure is indicated irrespective of the time at which it occurs. Such treatment can be undertaken regardless of the pathophysiology of the elevated intracranial pressure (haemorrhage, infarction or swelling) [6].

INTENSIVE THERAPY I FOR SAH

Thomas Kerz

Department of Neurosurgery, Johannes Gutenberg University of Mainz,
Mainz, Germany

ABSTRACT

There are special features of the intensive medical care of patients with SAH that are essential to outcome. American as well as European recommendations do exist, and the American Neurocritical Care Society has also published its own recommendations [1-3]. Nevertheless, a recently published survey revealed that treatments offered to such patients vary considerably. This chapter tries to summarize evidence-based recommendations relevant to therapy, sedation, blood pressure, fluids and electrolytes.

Keywords: subarachnoid haemorrhage, intensive care therapy, cerebral vasospasm, hyponatremia, cerebral blood flow

1. SEDATION

By minimising sedation in ventilated patients, the length of stay in intensive care and ventilation time can be reduced [4]. If sedation is too deep, clinical examination of neurological patients is difficult and important findings may be obscured. On the other hand, insufficient sedation can result in increased cerebral oxygen consumption and elevated intracranial pressure. Most studies and recommendations focus on patients in mixed intensive care units, whereas only few studies have been published in regard to sedated patients with neurological damage. Therefore and until further studies are available, the recommendations for patients in general ICUs should be followed. In patients in neurological intensive care, analgesia-based sedation (fentanyl or remifentanyl) has achieved greater pain relief than sedatives (propofol or midazolam), albeit with an equal rate of unscheduled extubations [5]. Significant interindividual pharmacokinetic effects have been reported for midazolam in

neurological patients. In one study, midazolam or its active metabolite, 1-hydroxymidazolam glucuronide, was still detectable 67 h on average after ending the midazolam infusion. By measuring the concentrations, a higher percentage of patients with neurological damage could be distinguished from those with delayed recovery, since approx. three quarters of the patients with no measurable drug concentration died due to neurological damage or were severely affected, whereas approx. three quarters of the patients with measurable concentrations recovered completely [5].

In neurological patients without an increase in intracranial pressure requiring sedation for less than five days, daily neurological evaluation could be performed sooner after sedation with remifentanyl, if necessary together with propofol or midazolam, than after analgesia with fentanyl or morphine [6]. In patients with increased intracranial pressure or those requiring deep sedation due to unstable intracerebral pathologies, conventional sedatives can be administered. In a meta-analysis, no single regimen was found to offer any particular benefit over another [7]. Ketamine is no longer contraindicated – in fact, the substance is beneficial due to its sedative and analgesic properties [8]. After termination of sedation, O₂ consumption and energy turnover each increase by about 50% [5]. Withdrawal delirium is observed in approx. 15%-50% of all patients on general intensive care units [9]. No information is available on its frequency in neurointensive care patients. If vigilance deteriorates, a cranial CT scan should generally be taken to investigate the cause (hydrocephalus, secondary haemorrhage, ischaemia, etc.).

A comparison of dexmedetomidine and propofol in patients with SAH revealed that the incidence of bradycardia and hypotension is identical [10]. Whereas dexmedetomidine is often used in awake operations and has been found to convey cerebroprotective effects in animal studies, its potentially negative effect on cerebral blood flow (CBF) in humans has not yet been fully explained. Hence, no firm recommendation can be made as to its use in sedating patients with neurological conditions [11].

Inhalational anaesthetics lead to decoupling of CMRO₂ (cerebral metabolic rate of oxygen) and CBF, by decreasing the former and increasing the latter. In doing so, they could play a protective role against vasospasm-induced ischaemia. Isoflurane has resulted in an insignificant increase in ICP, but significant decreases in mean arterial pressure (MAP) and cerebral perfusion pressure (CPP, 6.5 and 6.3 mm Hg, respectively), despite raising the vasopressor dose [12]. The mean blood flow rates in the middle cerebral artery remained unchanged. In another study that compared isoflurane with propofol, regional CBF measured by thermodiffusion was markedly increased [13]. In approximately one third of patients, sevoflurane resulted in severe adverse reactions, including an elevation in ICP and a drop in MAP and CPP, necessitating discontinuation of drug administration [14].

Conclusion: All sedatives conventionally used in intensive care patients can also be applied in SAH patients.

2. BLOOD PRESSURE AND FLUIDS

Blood pressure and cardiac output play a pivotal role in terms of cerebral perfusion. Acute SAH is regularly associated with reduced cerebral autoregulation. Hence, CBF is directly related to MAP and cannot be maintained at a constant level by the cerebral vessels.

Triple H therapy, consisting of hypervolaemia, hypertension and haemodilution, has long been used as a means of increasing CBF in the presence of vasospasm. In the only available randomised study on this subject, however, hypervolaemia did not lead to an improvement either in CBF or the neurological outcome [5]. Prophylactic volume expansion and hyperdynamic therapy, even when introduced before development of vasospasm and after securing the aneurysm, also had no positive effect on CBF and no clinical benefit as compared to normovolaemia [15]. Only isolated case reports have demonstrated that such therapy is beneficial. The target values in such a case were a systolic pressure of 160 mm Hg before clipping the aneurysm and 240 mm Hg after, respectively [16]. However, significant adverse effects have also been reported: pulmonary oedema, hyponatraemia, secondary haemorrhage and coagulopathies. With respect to blood pressure management, randomised studies are lacking. Whereas dopamine was used in most of the earlier studies, phenylephrine, dobutamine or noradrenaline have been the focus of more recent studies, and vasopressin was also studied in another. Case series and cohort studies suggest that CBF is increased by approx. $10 \text{ ml} \cdot 100\text{g}^{-1} \cdot \text{min}^{-1}$ as a result of adjusting hypertensive blood pressure levels (systolic 160-200 mm Hg). Miller et al. reported an 88% improvement in the neurological deficits of their patients if hypertensive treatment was not commenced until after onset of the symptoms [17]. Neurological improvement was noted in 71% of patients in another study in which normovolaemic hypertension was modified to 25%-50% above the normal arterial systolic blood pressure by dopamine and dobutamine [18]. In line with these findings, CBF and cerebral oxygen tension (PtiO_2) increased as a result of hypertensive therapy [19], whilst hypervolaemia was associated with an increased rate of adverse reactions (pulmonary oedema, heart failure) [20]. Two studies have demonstrated that the CBF can be increased in patients with severe SAH by administering hypertonic saline [21, 22]. With respect to blood pressure and the treatment of concomitant Takotsubo cardiomyopathy [23, 24], levosimendan [25] or intra-aortic counterpulsation [26, 27] have been used in isolated cases. Therapeutic anticoagulation is necessary in case of the latter, however. In patients with further aneurysms in addition to a haemorrhaged and occluded aneurysm, induced hypertension with CPP values between 80 and 120 mm Hg (MAP 90-130 mm Hg) was not associated with an increased rate of bleeding [28]. Noradrenaline was mainly used in this study, if needed in combination with dopamine or dobutamine.

The study group of the Neurocritical Care Society recommends maintaining euvolaemia and avoiding prophylactic hypervolaemia. Isotonic solutions should be used for fluid replacement. If a negative fluid balance persists, hydrocortisone or fludrocortisone can be considered [2]. In general, higher blood pressure is accompanied by increased CBF; most studies noted an improvement in the neurological deficit in approx. two thirds of patients.

Conclusion: Isotonic solutions should be used for replacing fluids. Euvolaemia should be the goal.

3. ELECTROLYTES

Hyponatraemia is the most common form of electrolyte imbalance in SAH. It can occur with euvolaemia, hypervolaemia or hypovolaemia. The most common cause for euvolaemic or hypervolaemic hyponatraemia is the inadequate secretion of antidiuretic hormone (ADH).

Since it is not always possible to detect an excessive ADH concentration, the term “syndrome of inadequate antidiuresis” (SIAD) has been coined lately. Other signs are a urine osmolality of > 100 mOsm/kg and a urinary sodium concentration of > 30 mmol/L. The levels generally return to normal if water is restricted. To measure the increased reabsorption rate of sodium, fractional sodium excretion ($> 0.5\%$) is appropriate but can be falsified by the administration of diuretics. Fractional uric acid excretion has a positive predictor rate for SIAD of 100% at a cut-off of $> 12\%$ and is not distorted by diuretics [5].

Hypovolaemic hyponatraemia thus is usually accompanied by a urinary sodium concentration of < 30 mmol/L, fractional sodium excretion of $< 0.5\%$, and fractional uric acid excretion of $< 12\%$. Differentiation is complicated, however, as excessive diuresis and excessive reabsorption of free water sometimes occur simultaneously [29].

Determination of volume status is crucial to therapy, since hypervolaemic patients require diuresis whereas in euvoemia it would lead to unwanted fluid deficiency. Drug-wise, fludrocortisone and hydrocortisone can be administered. Hypertonic saline solutions or enteral administration of saline are likewise possible. Vasopressin receptor antagonists, such as tolvaptan, lead to free water clearance but can also cause excessive diuresis and therefore should only be used whilst closely monitoring the volume status [5].

Studies and meta-analyses have not found prophylactic treatment with magnesium to be beneficial in preventing a delayed ischaemic neurological deficit (DIND, [30]). The benefit in terms of avoiding hypomagnesaemia also has not been adequately demonstrated [31].

Conclusion: A thorough investigation of the causes and appropriate therapy are required if hyponatraemia is to be avoided. Magnesium replacement cannot be recommended.

Chapter 72

NEUROPROTECTION: DCI, VASOSPASM, NIMODIPINE

Christian Heinen

Department of Neurosurgery, Evangelical Hospital Oldenburg,
Steinweg 13-1726122 Oldenburg, Germany

ABSTRACT

Cerebral posthaemorrhagic vasospasm and delayed cortical ischaemia are dreaded complications associated above all with aneurysmal subarachnoid haemorrhage. These phenomena are also observed during traumatic SAH or inflammatory CNS disease [1]. Mortality in relation to SAH is approx. 50% and includes patients who die on the spot and do not reach a hospital. The mortality rate in patients receiving hospital treatment is still 25% regardless of all diagnostic and therapeutic options [2]. Vasospasms and delayed cortical ischaemia are entities that should each be considered individually. The clinical significance is the subject of much discussion.

Keywords: neuroprotection, delayed cortical ischemia, cerebral vasospasm

INTRODUCTION

In a meta-analysis, Frontera et al. reported that symptomatic vasospasms (clinical findings with no changes on imaging) occurred in 16% of patients, delayed cortical ischaemia (DCI) (clinical findings WITH changes on imaging) in 21%, angiographic vasospasms in 31% and on TCD in 45% [3]. This stresses the fact that morphological findings do not necessarily have to have a clinical impact and that there must be mechanisms which extend beyond simple vasospasm.

It is therefore important to be clear about the terms and to distinguish one from another.

CEREBRAL VASOSPASM - CVS

CVS basically means the pathological constriction of the cerebral arteries following SAH. In the literature, varying and sometimes contradictory forms of CVS, the clinical implications of which vary considerably, are grouped together under this generic term. Vasospasms detected on *angiography*, i.e., a decrease in the vascular cross-section compared to previous images, were described as early as 1951 [4]. The incidence is specified as 60%-70%. However, this is not necessarily associated with clinical deterioration. In contrast, CVS is found on *transcranial Doppler/Duplex* (TCD), and occurs in approx. 50% of all SAH patients. A relative constriction of the vessels is thereby measured indirectly from a change in blood flow velocity according to Poiseuille's Law. The difficulty with the term CVS is that, as already mentioned, it offers no indication of the clinical impact and refers merely to the vasoconstriction itself, without allowing for the other pathological mechanisms.

DELAYED CORTICAL ISCHAEMIA - DCI

The term delayed cortical ischaemia (DCI) was therefore introduced. Firstly, it refers to new changes revealed by CCT/MRI images e.g., constriction of the vessels, and also to ischaemia or perfusion deficits that were not identifiable on the initial scans. Secondly, symptoms of clinical deterioration are recorded. These include new-onset aphasia, unilateral symptoms, deterioration of the GCS (Glasgow Coma Score) by 2 points, neglect, or apraxia. The changes should last at least one hour, not have a direct temporal relationship to aneurysm treatment, and not be attributable to other diseases (infection/electrolyte imbalance/cardiac events, etc.) [5]. In 20%-30% of patients, DCI appears to be responsible for the severe neurological damage that develops as a secondary complication. In approx. 7%-10% this can even prove fatal [6], regardless of any particular treatment. The term DCI is therefore more broadly defined and does not focus on vasospasm alone.

The following sections provide a summary of the possible components that contribute to the development of DCI.

PATHOMECHANISM

A number of pathomechanisms are proposed as contributory factors in DCI. How it develops precisely, however, is still unclear. Besides disrupted autoregulation of the arterial system, inflammatory processes are of particular relevance. Ultimately, there is a preponderance of vasoconstrictive and obstructive agents with at the same time a significant reduction in antagonistic vasodilators. Basically, there are different phases of ischaemia in SAH.

The early phase ("early brain injury") occurs during acute rupture as global ischaemia due to the acute rise in intracranial pressure (ICP) with a consecutive decrease in cerebral perfusion pressure (CPP), and spans the first 72 hours after the bleeding occurs. It is posited that the consequences of this early damage sometimes are only seen over the course [7]. Acute vasospasm in response to the haemorrhagic extravasate has been described [8]. The

blood-brain barrier is permeated and autoregulation disrupted. During the *late phase*, a number of simultaneous processes takes place, leading to local structural change in the vascular wall with resulting intimal thickening and media proliferation [9].

In its physiological state NO, as a cGMP inducer, is an essential and potent vasodilator that is stored in pre- and postganglionic perivascular neurons.

However, NO has a high affinity to haemoglobin. The latter binds increasingly to NO during SAH decreasing significantly NO-levels as a vasodilator. SAH also leads to neuron reduction with an emphasis on NO deficiency. *Endothelin-1* is the most potent vasoconstrictor known [10]. Increased concentrations are found both in the cerebrospinal fluid and in the plasma of SAH patients; clinically these closely correlate with the occurrence of CVS [11, 12]. Endothelin-1 usually appears in astrocytes, neurons, smooth muscle cells and the endothelium. As a result of activating leukocytes in the cerebrospinal fluid, SAH appears to increase the production and in turn the secretion of endothelin-1 [13]. Various degradation mechanisms release *free radicals*, which damage cell membranes in the endothelium, smooth muscle cells and in vasoregulatory neurons. Additional vasoconstrictive substances such as arachidonic acids may be released through these cascade with a dysregulated calcium influx being the consequence [14]. Moreover, the increased development of *microemboli* and *cortical spreading depression (CSD)* seems to play a part in the emergence of DCI. Cerebral ischaemia was found in 77% of post-mortem examinations without any angiographic evidence of vasospasms [15]. A combination of pathologically activated coagulation and simultaneously decreased fibrinolysis is believed to be responsible for the formation of *microemboli* [16].

CSD describes waves of depolarisation spreading through the grey matter.

This occurs spontaneously in SAH and lasts longer than the otherwise usual 5-15 minutes. In healthy individuals, vasoconstriction occurs shortly before CSD, followed by vasodilation during the CSD phase (spreading hyperperfusion) and a phase of reduced and delayed tissue perfusion during the recovery phase after the CSD wave [17]. However, the vascular reaction is altered in SAH patients. Therefore, the CSD can lead either to no change in the vascular width or to a pathological vasoconstriction known as *cortical spreading ischaemia* [18] without a relaxation phase. If CSD occur more and more frequently in quick succession, the affected areas of cortex cannot recover from the hypoperfusion. CSD occurs more often between day 5 and 7 post haemorrhage [19].

NEUROPROTECTION

Numerous strategies have arisen based on recent insights into the pathological mechanism. The therapeutic options that are actually available for treating or preventing DCI, however, are rather sobering. Despite all efforts, the calcium channel blocker nimodipine constitutes the drug with the only evidence to date of a significantly better outcome. An overview of the pharmacological and non-pharmacological options and their impact is provided in the following few paragraphs (see also Table 1 and 2).

Table 1. Overview substances and recommendation level

Substance	Mechanism of action	Indication	American Stroke Association recommendation
Ca ⁺⁺ blocker	Vasodilation/anti-inflammatory	Prevention and treatment of CVS/DCI	Yes
Mg ⁺⁺	Vasodilation/(anti-inflammatory)	Prevention of CVS	No
Statins	Anti-inflammatory, improved endothelial function	Treatment of CVS	No
Anti-epileptics	Anticonvulsive/diminished cortical spreading depression	Treatment of convulsions	No
Aspirin	Platelet aggregation inhibition	Prevention of DCI	No
Glucocorticoids	Anti-inflammatory	Prevention of CVS	No
Enoxaparin	Antithrombotic	Prevention of DCI	No
Tirilazad	Membrane stabilisation	Treatment of CVS	No
Clazosentan	Vasodilation	Treatment of CVS	No

CVS: cerebral vasospasm DCI: delayed cerebral ischemia

PHARMACOLOGICAL

Nimodipine

Nimodipine is a dihydropyridine and therefore a selective Ca⁺⁺ channel blocker. It binds to the voltage-dependent L-type Ca⁺⁺ channels and appears to have an increased affinity to cerebral and renal vessels. In Europe both oral and intravenous pharmaceutical forms are available, whereas in the USA only oral administration is approved.

Intra-arterial administration via an intracranially placed microcatheter is also possible [20]. There have also been reports of intrathecal doses [21]. In comparative studies, the efficacy of intravenous and oral doses did not differ [22, 23]. Those studies that were able to demonstrate efficacy were based on oral intake [24]. It is important to mention that many of the nimodipine studies were carried out many years, sometimes decades ago, but the results are still valid in terms of clinical routine [24, 25]. The only larger-scale study to which reference is still made and which on meta-analysis suggests that nimodipine has a significantly better outcome, dates back to 1989 [26]!

Neuroprotection

The original assumption that the positive effect was derived merely from vasodilatation has more recently been revised. In contrast to other Ca⁺⁺ channel blockers, nimodipine obviously has other neuroprotective properties, particularly after SAH. However, its exact mechanism of action has not yet been fully explained. Nimodipine plays a part in activating fibrinolysis, which may then attenuate the development of microthrombi [27]. It also prevents uncontrolled Ca⁺⁺ influx into the neurons subsequent to an ischaemic event. This influx would normally lead to neuronal cell destruction [28]. In rat model nimodipine seemed also to attenuate CSD [29].

Intra-Arterial

Intra-arterial administration of nimodipine is considered in particular for refractory or rapidly recurring CVS and DCI [30, 31]. In addition to adverse drug reactions, the risks associated with the surgical procedure such as thrombosis, vascular perforations, air embolisms etc. must be taken into account [32].

Intrathecal

As early as 1982, Auer et al. described the local intrathecal use of nimodipine in the prevention of symptomatic vasospasm [33]. This idea was revisited over the course, whereby nimodipine was administered via lumbar drain and not locally as during clipping procedure [21].

However, the validity of the efficacy data is limited given that larger comparative studies are not available. Other Ca^{++} channel blockers have also been applied locally via an external ventricular drain, a catheter placed in the circle of Willis, or as pellets. There are no clear recommendations due to the lack of larger-scale randomised studies, however [34].

Adverse Reactions

The side effect profile of nimodipine is broad. Pulmonary arteriovenous shunts with consecutively impaired gas exchange, hypotension, thrombopenia, allergic reactions and gastroparesis can occur. Reciprocal interactions occur (according to the package leaflet from Bayer) with certain antibiotics (e.g., erythromycin, quinupristin/dalfopristin), HIV drugs (e.g., ritonavir), certain antimycotics (e.g., ketoconazole) and antidepressants (e.g., nefazodone, fluoxetine), antiepileptics (e.g., valproic acid).

Triple-H Therapy: Hypertension/Hypervolaemia/Haemodilution

The principle behind triple-H therapy is to maintain perfusion by increasing the arterial pressure and decreasing viscosity (according to Poiseuille's Law) in the case of vascular dysregulation [35]. This is based on the observation that SAH patients developed new neurological deficits in the event of hypotension. Responses to triple-H therapy were recorded as early as the 1950s [36]. This method was and remains widespread, although there is still no clear evidence of its effectiveness. Meta-analyses performed in 2004 and 2010 did not reveal advantage from either combined triple-H therapy or the individual components (hypervolaemia/hypertension only, etc.) [37]. In contrast, hypervolaemia would appear to result in more complications [38]. At present, euvolaemia and "mild hypertension" are therefore recommended [39].

Magnesium

Mg^{++} is a competitive blocker of voltage-dependent calcium channels. Its effect ranges from vasodilatation, inhibition of platelet aggregation, and improvement in erythrocyte elasticity, as far as stabilisation of the endothelium [34]. Other neuroprotective effects have been detected experimentally [40]. Interestingly, hypomagnesaemia occurs in approx. 50% of

all SAH patients. It can be used as a predictor of DCI, particularly between day 2 and 12 post haemorrhage [41]. Despite the high expectations for Mg^{++} , no evidence of a positive effect on the outcome has been forthcoming – large-scale studies (e.g., MASH-II study) notwithstanding [42]. There is no clear recommendation for routine use in SAH [39].

Statins

As stabilisers of the endothelium, platelet adhesion/aggregation inhibitors and anti-inflammatory agents, statins seem predestined for neuroprotection. However, neither meta-analyses nor a large-scale, multicentre, randomised, double-blind phase 3 study managed to identify a significant difference between simvastatin and a placebo [43-45]. Statins thus are not used routinely at present.

Endothelin-1 Receptor Antagonists

As already mentioned, endothelin-1 (ET-1) is the most potent vasoconstrictor known. The first study used the non-selective ET-inhibitor TAK-044 [46], without achieving any significant improvement. Subsequently, other study groups demonstrated an improvement in the angiographic vasospasm and the occurrence of delayed ischaemic neurological deficits (DIND) with the specific ET-1-inhibitor clazosentan. However, outcome was not more favourable [10]. Moreover, significant adverse effects such as pulmonary oedema, anaemia and hypotension [47] occurred, and the subset of clipped patients showed a poorer response. The study (CONSCIOUS-2) was discontinued and the planned follow-up study, CONSCIOUS-3, was not even started [35].

Other Substance Classes

There are numerous other literature references concerning neuroprotection in SAH. Various substances such as corticosteroids, radical scavengers (tirilazad), aspirin, low-molecular-weight heparins, metalloproteinases, progesterone/oestrogen, antiepileptics and antifibrinolytics, have been studied for their suitability as neuroprotective agents in SAB [47-49]. But, none of them proved satisfactory.

NON-PHARMACOLOGICAL

Interventional

Intracerebral

Aside from the intra-arterial administration of nimodipine discussed above, balloon dilatation in the treatment of refractory symptomatic vasospasms also plays an important role. The best outcomes are achieved if treatment ensues within two hours after onset of the

symptoms [50]. Because material from the coronary angiography had to be used in the initial phase, the material has improved considerably in the last few years. At the same time, growing expertise has helped to lower periprocedural complications and improve the results, even in the case of multiple treatments [51] (see Table 2).

Intra-Aortic Counterpulsation

As an adaptation of the treatment for cardiogenic shock, this method involves the intra-aortic insertion of a balloon proximal to the cerebral vessels. If the aortic valve closes, it is inflated so as to increase the diastolic cerebral arterial flow [50].

Hypothermia

Evidence was found that hypothermia has a positive effect on mean flow velocity in the middle cerebral artery in the case of both increased ICP and DCI. This is still to be confirmed by larger studies [52].

Stellate Ganglion Block (SGB)

The potential efficacy is based on the assumption that noradrenergic sympathetic innervation of the cerebral vessels originates largely from the superior cervical ganglion. Consequently, this system has a vasoconstrictive effect. Vasorelaxation is therefore achieved by blocking this ganglion. The technique is simple: infiltration at the transverse process of C6 using approx. 8-10 ml of a local anaesthetic. In spite of the vasodilation (measured indirectly from the TCD), autoregulation seems to be preserved when blocking the stellate ganglion [53]. One study of clipped SAH patients (n = 15) revealed that both a clinical improvement and a drop in TCD flow rates were achieved [54]. Since larger studies have not yet been conducted, the role of such a concept cannot be reliably judged.

Table 2. Evidence level of measures in refractory cerebral vasospasm

	Administration	Effect	Evidence level
Hypertension	IV	MAP increase	B
Balloon angioplasty	IA (cerebral)	Mechanical dilatation	B
Drug-eluting angioplasty	IA (bolus/continuous)	Vasodilation/anti-inflammatory	C
Intra-aortic counterpulsation	IA extracerebral	Increased cerebral perfusion	C
Ca ⁺⁺ channel blockers	Intrathecal	Vasodilation/anti-inflammatory	D
NO	Intrathecal	Vasodilation	D
Hypothermia	Systemic		D
Stellate block	Stellate ganglion	Vasodilation	D

IV: intravenous MAP: middle arterial pressure IA: intra-arterial

Figure 1. possible treatment algorithm.

CONCLUSION

There is no consistency in the terminology as regards CVS and DCI, meaning that vasospasm (on angiography/TCD), DIND and DCI are often used synonymously. DCI can also occur **WITHOUT** morphological changes, as various pathomechanisms occur simultaneously and do not necessarily lead to vasoconstriction. However, it is of utmost importance to recognize and treat these pathologies (see proposed treatment algorithm Figure 1). Despite intensive research at all levels, DCI therapy is still proving futile. Orally administered nimodipine is the only medicine to date that has exhibited a neuroprotective effect specifically in SAH. Hopefully, with growing knowledge of the pathophysiological background and translational studies, it will be possible to develop additional, effective treatment options. At the same time, it would be desirable to have reliable and easily detectable biomarkers for DCI with a view to establishing the diagnosis as well as monitoring treatment. Genetic factors that predispose patients to DCI may be the key to identifying and treating patients [55, 56] (Figure 1).

Chapter 73

INTENSIVE CARE: MONITORING

Werner Klingler^{1,2} and Dirk Repkewitz²

¹Division of Neurophysiology, Ulm University, Ulm, Germany

²Department of Neuroanaesthesiology, Neurosurgical Ulm University Hospital,
Guenzburg, Germany

ABSTRACT

Besides direct and indirect cerebral lesions, subarachnoid haemorrhage (SAH) may cause severe alterations of metabolism as well as cardiac, pulmonary and other medical complications. Specialized intensive care is required to improve neurological outcome and overall survival. This chapter covers monitoring of patients suffering from SAH in the intensive care unit (ICU). Prudent observation and evaluation of these parameters helps to manage the course of disease.

INTRODUCTION

Intensive care in specialized neurocritical care centers is associated with a lower mortality and better outcome in SAH compared to general ICU's (Kurtz et al. 2011). Multimodal cerebral monitoring including clinical examination, assessment of cerebral perfusion, intracranial pressure and other specific parameters is essential for an individualized treatment plan and for prevention of secondary brain injury (Figure 1). This chapter focuses on ICU monitoring after the initial SAH. In this critical time interval there is a high risk for re-bleeding, epileptic seizures and/or delayed cerebral ischemia (DCI) due to vasospasm. Indeed, vasospasm can occur up to roughly 20 days after the initial event and is associated to mortality, functional and cognitive disability (Le Roux et al. 2014, Lantigua et al. 2015).

Despite the brain weighs only roughly 2% of lean body mass, it is allocated 20% of cardiac output at rest. Perfusion and oxygenation are crucial for cerebral energy metabolism, which is primarily based on glucose degradation and the respiratory chain. Early detection of an imbalance between cerebral oxygen supply and demand is relevant to outcome in these patients (Diringer et al. 2009).

CLINICAL EXAMINATION

Whereas the initial presentation of SAH is characterized by severe headache, meningism and neurological impairment, the later course of symptoms varies significantly, most notably during ICU treatment. Here, detection of re-bleeding and vasospasm is of vital importance. Clinical examination of SAH patients is fast and focuses on vital signs, level of consciousness and motor responses. Asymmetric motor responses or partial epileptic seizures may be an indication of focal brain lesion hinting towards vasospasm. In awake patients one of the first signs of a developing vasospasm usually are cognitive deficits such as an attention deficit or change in conscious state. Quantification of the level of consciousness is best achieved by structured assessment of sedation and agitation. Several clinical grading scales have been developed. The Glasgow Coma Scale is widely known, however it is only validated for traumatic brain injury. Instead, the Richmond Agitation Sedation Scale (RASS) is designed for ICU use and has the advantage of a high validity and interrater reliability (Ely et al. 2003).

In unconscious patients, a key element is the examination of the pupillary light reflex, which integrates the optic and oculomotor nerves and brainstem nuclei. Instrument-based documentation of pupillary function is commercially available. The oculomotor nerve partially controls eye movements and activates the ciliary muscle, via parasympathetic fibers, i.e., miosis. The oculomotor nerve trails along the base of the brain and is especially vulnerable to direct pressure lesions or secondary damage. Up to one third of SAH patients show intraocular hemorrhage, known as Terson's syndrome. This phenomenon likely occurs due to elevated ICP. Other symptoms of elevated ICP include cephalgia, nausea and vomiting including cranial nerve palsies. Indeed, persistent ocular divergence, ocular bobbing, lack of pupillary light reflex, unequal or irregular pupils are signs of severe brain damage and associated with poor neurological prognosis. Damage of the autonomous nuclei in the brainstem leads to pathological breathing patterns, cardiac arrhythmia and finally death (Miyata et al. 2014).

MONITORING OF THE INTRACRANIAL PRESSURE (ICP)

ICP monitoring allows an estimation of cerebral perfusion by calculating the perfusion pressure as the difference between mean arterial pressure and ICP (see chapter 13).

In over 90% of SAH patients some degree of elevated ICP is found, mainly within the first 8 days after the bleeding. The Hunt and Hess grade correlates with the degree of ICP elevation. Mortality is increased in those patients, which have significantly elevated post-SAH ICP levels (Lv et al. 2015). Hence, ICP monitoring is advisable in those patients showing clinical or radiographic signs and symptoms of elevated ICP, especially in sedated patients (chapter 9). Invasive ICP monitoring is used significantly more frequently in neurocritical care units compared to general ICU's. Whether ICP-directed therapy is causative for better outcome in these specialized units has not been shown yet (Kurtz et al. 2011). There are several methods for assessment of ICP. Most centers use ventricular catheters, which have the advantage of potential use for CSF drain in order to reduce intracranial volume and also to obtain material for microbiological analysis. Other possibilities include the insertion of a

small pressure sensor via a small drill trepanation. The sensor can be placed in the epidural, subdural, subarachnoid or parenchymatous space (Diringer et al. 2011)

TRANSCRANIAL DOPPLER ULTRASONOGRAPHY (TCD)

Roughly 30 – 70% of SAH patients show radiographic evidence of vasospasm, but only half of those experience neurological symptoms. Clinical signs of vasospasm fluctuate and often are unspecific. The frequent use of sedatives in SAH patients further limits clinical evaluation (Kistka et al. 2013, Le Roux et al. 2014). Vasospasm is detected by cerebral angiography with high sensitivity and specificity. TCD bridges the gap between physiological and radiological examination. The main advantage of TCD is its non-invasive nature and bedside evaluation. However, analysis is limited to the blood supply originating from trunk of the middle cerebral artery. Technical problems such as inadequate insonation window or interrater variability account for moderate sensitivity, especially in the assessment of the outflow into the anterior cerebral artery. In other words, TCD is an easy applicable method with a high predictive value for vasospasm detection predominantly of the middle cerebral artery. Increased flow velocities ($> 120\text{cm/s}$), most notably in combination with clinical suspicion of vasospasm, should prompt additional investigations such as diagnostic imaging (see chapter 9).

Figure 1. Neurocritical care including intracranial pressure monitoring and brain oxygenation monitoring [1], processed EEG [2], continuous cardiac output monitoring [3], ECG, invasive blood pressure, SpO₂, pCO₂, temperature monitoring [4] and TCD [5].

NEAR-INFRARED SPECTROSCOPY (NIRS)

NIRS is another non-invasive method for estimation of cerebral perfusion. Absorption of specific near-infrared wavelengths (700-1000nm) depends on tissue oxygenation and mitochondrial oxygen metabolism. Thereby cerebral hypoperfusion, e.g., in carotid surgery or

temporary clipping, can be detected intraoperatively. In the ICU, NIRS may detect vasospasm but also impairment of cerebral autoregulation. However, NIRS electrodes mainly cover the frontal lobe and are vulnerable to sweat and other obstacles impairing electrical impedance (Zweifel et al. 2010).

BRAIN OXYGENATION MEASUREMENTS AND CEREBRAL MICRODIALYSIS

Even if cerebral perfusion pressure and other parameters are normal, neuronal metabolism may be impaired in SAH. In these conditions, an accumulation of acidic metabolites as well as a drop of brain tissue oxygenation (ptiO₂) and pH can be observed by tissue microdialysis. Several studies suggest a link between regional ptiO₂ and vasospasm respectively impaired autoregulation. However, sample sizes are small and results not fully consistent (Kistka et al. 2012). Several metabolic markers can be measured using microdialysis. Glycolytic metabolites include glucose, lactate and pyruvate. Neuronal degradation goes along with an increase in glutamate, nitrite and taurine concentrations. These parameters as well as the lactate/pyruvate ratio may even be prognostic markers for neurological outcome (Sarrafzadeh et al. 2004). A pre-requisite and limitation is the necessity of an invasive implantation of a microcatheter into the relevant brain region and the sensors are only monitoring a localized region of the brain. A modification of the above described microcatheters is a thermal diffusion flowmetry probe. This intracerebral microcatheter contains a temperature sensitive electrode, which detects heat signals emitted by a gold electrode of the same device. The time delay is a measure for local cerebral blood flow (Kistka et al. 2013).

BIOMARKERS

The occurrence of neuronal degradation products, enzymes and specific proteins in the cerebro-spinal fluid (CSF) of SAH patients supports the concept of monitoring these biomarkers for prognostication and vasospasm detection. A well recognized feature of SAH is a centrally mediated sympathetic response. Indeed, increased CSF and blood levels of epinephrine are independent prognostic predictors of poor prognosis. One of the best studied biomarkers in SAH is the calcium-binding glial protein S100 β . Brain lesions of various aetiology lead to release of S100 β , which is not only found in elevated concentrations in the CSF but to a lesser extent also in peripheral blood. S100 β may be a prognostic biomarker of SAH, but it does not seem to be a specific indicator for vasospasm or DCI. Neuro-inflammatory response is a key element in the pathophysiology of SAH. Indeed, acute phase proteins such as C-reactive protein or cytokines, e.g., TNF- α and IL-1 β are variably and asynchronously upregulated in SAH. IL-1 β and other cytokines are endogenous pyrogens that impair thermoregulation. Other proteins, which are released in brain damage, are for example neuron-specific enolase, apolipoprotein E, amyloid β protein and creatine kinase BB. High CSF concentrations of those proteins may indicate poor outcome. A promising approach is the investigation of vasogenic biomarkers because there are indications, that vascular

endothelial growth factor and the vasoconstrictive substance endothelin-1 is elevated in SAH (Hong et al. 2014). In conclusion, analysis of biomarkers may help for the differentiation between re-bleeding and vasospasm. Currently, its use in SAH is still limited due to the need for sophisticated laboratory technology and lack of point of care specificity.

ELECTROPHYSIOLOGICAL MONITORING

Vasospasm and non-convulsive epileptic seizures are frequent complications of SAH but difficult to detect in the unconscious patient. Electroencephalography (EEG) is a tool to assess electrical brain activity. The electrical signal of the EEG recording is based on summation of depolarization events in neighbouring brain cells, most notably of postsynaptic potentials of apical cortical neurons. In contrast to the ECG waveform, the registration is characterized by scattered potentials. Amplitude and frequency of the EEG signal are indirect markers for synchronicity of neuronal excitation (Table 1). A decrease in the Alpha/Delta frequency band ratio is associated with delayed cerebral ischemia due to vasospasm (Claassen et al. 2004). EEG can also detect epileptic seizures, which in SAH patients are often a hint for aneurysmal re-bleeding. Non-convulsive seizures occur in 10-20% of comatose SAH patients and in some patients may explain unconsciousness (Kistka et al. 2013, Lantigua et al. 2015).

The question arises, whether the main goal for the prevention of DCI may be achieved by using modified EEG recordings, which are already in use for the analysis of the depth of sedation and have the advantage of easy interpretation. Processed EEG parameters, such as the bispectral index and the suppression ratio have been shown to have prognostic value concerning neurological outcome following hypoxic brain damage (Selig et al. 2014). Potential use of such devices in stroke/vasospasm detection is currently under investigation. Similarly the use of evoked potentials is still controversial for outcome prognosis or early detection of vasospasm in the ICU, although evoked potentials are frequently used during aneurysm surgery to indicate a loss of neuronal function respectively diminished local blood perfusion (Wachter et al. 2011). All discussed electrophysiological methods are difficult to integrate in the ICU due to technical pitfalls such as electrical noise fields, nursing care as well as requiring specific expertise for the application and interpretation of the complex signals (Le Roux et al. 2014).

Table 1. EEG-frequency bands and level of consciousness

Frequency range	Label	Symbol	Level of consciousness
0,5-4 Hz	Delta	δ	deep sedation, trance
4-8 Hz	Theta	θ	hypnosis
8-13 Hz	Alpha	α	awake, closed eyes
13-30 Hz	Beta	β	awake, concentrated, REM sleeping cycle
30-42 Hz	Gamma	γ	high information flow

Reduced metabolic activity due to e.g., hypoxia or sedative drugs results in synchronisation of potentials and reduction of EEG frequency.

CARDIO-RESPIRATORY MONITORING

Arterial blood pressure is a hemodynamic index, most relevant for goal-directed therapy in SAH patients (chapter 13). Correct evaluation of blood pressure is not simple, there are pitfalls in the technical assessment but also since the pressure pulse waveform depends on the point of measurement. Invasive blood pressure monitoring is superior to non-invasive methods both in terms of accuracy and time restraints (Kim et al. 2014). The insertion of an arterial line is rarely associated with complications such as infection, bleeding or thrombosis. Non-invasive blood pressure readings disguise hypotensive intervals by overestimating systolic arterial blood pressure resulting in elevated ICU mortality compared to invasive blood pressure monitoring (Lehman et al. 2013).

Physiologically, systolic arterial blood pressure is roughly 20mmHg to 40mmHg higher in the legs than in the arms even in supine position. Systolic blood pressure rises and blood flow velocity decreases with increasing distance from the heart, which results in different pulse waveforms. Hence, the mean arterial pressure (MAP) as the geometric mean of the pulse wave is the best parameter for therapeutic decisions. Continuous cardiac output monitoring and evaluation of stroke volume variability may be helpful in some patients, most notably for evaluation of the dilemma volume versus adrenergic drugs (Lehman et al. 2013).

Figure 2. ECG alterations in SAH. Dysrhythmia and ST-segment abnormalities.

Figure 3. Neurogenic pulmonary edema.

ICU monitoring further requires continuous electrocardiographic (ECG) monitoring, because 50-100% of patients present cardiac arrhythmia and/or signs of myocardial ischemia as a consequence of the SAH induced adrenergic surge (Cushing's reflex). ST-segment abnormalities (Figure 2) may be the primary reason for hospital admission. Myocardial stress markers, such as Troponin, N-terminal end of the prohormone brain natriuretic peptide (NTproBNP) and CK-MB may be elevated in SAH patients. Similarly, lung insufficiency of variable degree is a well recognized complication of SAH and causes up to 30% of deaths after SAH. Mascia (2009) introduced a double hit model of lung injury after severe brain lesion. The initial adrenergic reaction hits the lung by constriction of pulmonary veins resulting in pulmonary hypertension, increasing hydrostatic pressure, cardiac burden and ventilation/perfusion deficit. The second hit is mediated by a systemic inflammatory response syndrome, which not only causes an increase of the permeability in the blood-brain barrier, but also causes leaky lung capillaries. Inflammatory neuropeptides activate neutrophil infiltration into the lungs, which cause further deterioration of pulmonary function. The lungs are then even more vulnerable to mechanical stress of invasive ventilation. Apart from neurogenic pulmonary edema (Figure 3) there are other reasons impairing pulmonary function such as respiratory tract infections, aspiration, pulmonary embolisation and drugs influencing pulmonary shunt (Mascia 2009, Diringier et al. 2011, Lantigua et al. 2015). Vasodilating drugs, most notably nimodipine, hamper the physiological vasoconstriction of non- or low-ventilated alveoli, thus increasing pulmonary shunt. The above mentioned mechanisms might be one reason, why lungs are rarely viable for organ donation after severe brain injury. Furthermore, pCO₂ has to be monitored closely in SAH because of its key role in controlling cerebral blood flow (chapter 15).

GENERAL CONSIDERATIONS

General considerations in SAH include monitoring of hemoglobin and of the coagulation system for obvious reasons. A key factor in SAH monitoring are glucose levels, because there is strong evidence that hypo- as well as hyperglycemia is associated to poor neurological outcome. Further parameters include hormones and electrolyte levels (chapter 13). Tight monitoring of temperature is indispensable in SAH patients as thermoregulation is impaired in this group of patients. Neurogenic, non-infectious fever usually occurs within the first 3 days of admission and has a higher incidence poor grade SAH and in those patients with intraventricular bleeding. Common causes of infectious fever include catheter infections, respiratory tract infections or ventriculitis. Aggressive temperature control is indispensable and achieved by pharmacological and physical cooling including intravascular cooling catheters. Surprisingly, therapeutic hypothermia has failed to show a benefit in SAH (Karnatovskaia et al. 2014). Other medical complications include thrombocytopenia, hepatic and renal dysfunction. The gastrointestinal function is often impaired due to adrenergic reflexes and neurogenic inflammatory response. Osmotic stimulation of peristalsis and early enteral nutrition is beneficial to prevent secondary complications as gastrointestinal bleeding or ileus (Diringier et al. 2011, Le Roux et al. 2014, Lantigua et al. 2015).

SUMMARY STATEMENT

Survival and neurological outcome after SAH depends on specific complications such as vasospasm and re-bleeding but also on a variety of general medical parameters. Specific monitoring is essential for management of SAH patients. Detection of vasospasm is essential but not trivial, because all discussed methods have limitations. Recognition and treatment of the typical medical complications of SAH is another key element in the management of SAH-patients. Hence, multimodal monitoring and specific neurocritical care is a decisive factor for overall outcome.

ENDOVASCULAR TREATMENT OPTIONS FOR CEREBRAL VASOSPASM AFTER SPONTANEOUS SUBARACHNOID HAEMORRHAGE

Yigit Ozpeynirci and Bernd Schmitz

Section Neuroradiology, University of Ulm, Günzburg, Germany

ABSTRACT

When vasospasm is suspected in a patient with subarachnoid haemorrhage, medical treatment is usually the first choice. Unfortunately, vasospasm is often refractory to medical therapy and, moreover, the percentage of patients who cannot tolerate mainstream non-invasive treatment, usually due to cardiopulmonary complications, is not minute. Early endovascular treatment appears to be the best alternative for this group of patients.

Endovascular treatment of cerebral vasospasm is divided into two categories: chemical dilatation of the spasm by intra-arterial administration of vasoactive drugs, and transluminal balloon angioplasty of spastic segments. Flow augmentation strategies involving aortic obstruction with balloons are being actively investigated. However, they have not yet found a place in current practice.

Keywords: vasospasm, endovascular, angioplasty

GENERAL INDICATIONS FOR AND TIMING OF INVASIVE INTERVENTIONAL MANAGEMENT

In their guidelines, the American Heart Association (AHA) and American Stroke Association (ASA) consider endovascular therapy as reasonable in patients with symptomatic cerebral vasospasm (CV), recommending it in particular for those who do not rapidly respond to hypertensive therapy (Class IIa; Level of Evidence B) [1].

Endovascular intervention is often performed in patients who, despite intensive medical therapy, have a diminishing neurological status, develop sudden focal neurological deficits or in whom there is concern regarding complications from medical management. In many poor grade SAHs, however, routine clinical examination is not sensitive to acute changes in neurological status, since most of these patients are already comatose. The same applies to intubated and sedated patients. In these patients, the physician therefore has to rely on serial non-invasive imaging studies and it would be wise to treat moderate to severe CV revealed by such studies and confirmed by digital subtraction angiography (DSA).

Transcranial Doppler ultrasound (TCD) is an easy-to-perform bedside method which can be used on a daily basis during the vasospasm-sensitive phase to detect rising flow velocities. It is also helpful in the follow-up of patients after treatment.

CT angiography (CTA) supported by CT perfusion (CTP) is more sensitive than TCD in the detection of CV. CTP is able to illustrate the perfusion at tissue level and thus is sensitive to CV of both proximal and distal arteries. It is a very helpful in demonstrating delayed cerebral ischaemia (DCI) and impending infarction in intubated patients or patients with low Glasgow Coma Scores (GCS) [9] (Figure 1).

(A)

(B)

Figure 1. (Continued).

(C)

(D)

(E)

Figure 1. The Mean Transit Time (MTT) map (A) shows prolongation in both ACA territories and the right MCA territory without deficient perfusion on the CBV map (not shown). CTA demonstrates severe CV (B and C). DSA confirms the severe CV on the right (D). Control DSA 10 days after continuous IAIT with nimodipine reveals complete resolution of CV (E).

Angiographic findings of CV consist of decreased luminal calibre, increased cerebral circulation time and in severe cases retrograde filling of the affected vascular territory through leptomeningeal collaterals.

Studies suggest that there is a 2h time window after symptom onset in most patients during which endovascular therapy will be beneficial [2, 3, 4, 5, 6, 7, 8]. Thus it is reasonable to frequently check the neurological status of awake patients and assess the flow velocities of cerebral arteries via TCD in the patient with lower GCSs.

ENDOVASCULAR PROPHYLAXIS

As prophylactic transluminal balloon angioplasty (TBA) is related to very high mortality and has not been found to have a positive effect on outcome, and the therapeutic effects of all drugs administered IA are transient, CV prophylaxis is not recommended [1, 7].

INTRA-ARTERIAL INFUSION THERAPY (IAIT)

Several vasodilator agents have been infused intra-arterial (IA) through transarterial catheters to treat patients with CV. They include phosphodiesterase inhibitors (papaverine, milrinone and amrinone), calcium channel blockers (nimodipine, verapamil, nicardipine), protein kinase inhibitors (fasudil hydrochloride) and adenylyl cyclase activators (colforsin daropate hydrochloride) [5, 6]. The main effect is a temporary relaxation of smooth muscle cells in the vascular wall, causing vasodilatation.

There have been no randomised clinical trials to demonstrate the benefit of intra-arterial infusion therapy (IAIT) over medical therapy alone. The data is mostly based on large case series [10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23]. Nimodipine is the most intensively studied, and only, drug approved by the US Food and Drug Administration for use in the treatment of CV. According to the studies, IA nimodipine is safe and effective in the treatment of CV. Angiographic improvement in up to 43% of interventions and clinical improvement in 76% of treated patients were achieved using IA nimodipine [12, 13, 23]. This so-called clinicoangiographic dissociation has been explained by the presumably neuro-protective effects of nimodipine.

The drugs can be injected through selective or superselective catheterisation. Super-selective catheterisation would only be prudent where two circulations are unevenly affected distal to a bifurcation. However, in most patients only selective catheterisation would be enough to effectively treat CV and the risk of thrombus formation in a superselectively catheterised vasospastic artery is very high.

The methods involve either slow bolus administration of drug or prolonged infusions lasting approximately 30 to 120 min, or a combination of the two methods. Follow-up angiography is usually performed 10-15 minutes after the injection. A typical IA infusion dose of nimodipine per vessel is 1 to 2 mg over 10 to 30 minutes (total dose not exceeding 4 to 5 mg). If a significant effect is observed, the procedure can be ended and the patient returns to the intensive care unit for further follow-up. When required, multiple sessions have to be performed in order to achieve a better outcome. Some authors therefore prefer to leave the

introducer sheath in the artery during the sensitive period to avoid multiple femoral punctures in case of recurrent CV. If a minor angiographic effect is seen, continuous infusion therapy could be considered. The catheter will be left in the artery and continuous infusion therapy initiated, starting from 2 hours and lasting up to 10 days. Depending on the duration of the therapy the infusion rates of nimodipine vary between 1 and 6 mg/h.

At our institution, we usually treat severe CV with IAIT via indwelling catheters. Mostly it takes 5-7 days to return the size of the cerebral arteries to normal, but we have had a few patients in whom the IA catheters remained *in situ* for 10 days without significant complications (Figures 2 and 3).

Figure 2. (Continued).

(F)

(G)

(H)

Figure 2. (Continued).

(I)

Figure 2. The Mean Transit Time (MTT) map (A) shows prolongation in the left MCA territory with deficient perfusion on the CBV map (B) in the posterior insula. CTA (C and D) and DSA (E) images confirm severe CV of the proximal and distal arteries on the left. DSA (F) performed after 8 days of continuous IAIT with nimodipine demonstrates significant regression of CV. The arrow indicates the ruptured and coiled aneurysm in the left MCA. MRA (G) 7 days after IAIT shows arteries of normal size. On DWI (arrows on H and I) the infarctions in the left posterior insula and right cerebellum are visible. No significant complications related to the treatment of CV.

(A)

Figure 3. (Continued).

(B)

Figure 3. The distal markers of the indwelling microcatheters for continuous IAIT are illustrated (arrow on A). They lie in each petrous segment of the ICA. At B the distal tip of the guiding catheter can be seen in the descending aorta (arrow on B). The guiding catheter is usually placed at such a level to avoid injuring a vessel.

If no effect is observed, another therapy regimen should be considered.

The agents can be injected without danger to treat CV regardless of the vessel size and orientation. However, care should be taken when injecting Nimotop (Bayer, Leverkusen, Germany), since the solution contains 23.7vol% ethanol (alcohol) and interactions with alcohol-incompatible drugs can occur.

Verapamil and nicardipine are the next two drugs whose use is being increasingly reported in the literature [10, 14, 15].

SPECIFIC CONSIDERATIONS REGARDING IAIT

Delayed onset of action, a transient therapeutic effect and the potential increase in intracranial pressure (ICP) are some of the disadvantages of IAIT. IA nimodipine may increase the ICP by extravasation of fluid into the interstitial space in the brain or decrease the blood pressure through systemic vasodilation. Both have the potential to lower the cerebral perfusion pressure (CPP) with subsequent ischaemia in especially delicate vasospastic areas. Therefore, direct monitoring of ICP is necessary for excluding such a risk.

In order to prolong the effects of IAIT and avoid multiple sessions, nimodipine can be infused continuously via indwelling arterial microcatheters placed in the internal carotid

artery or vertebral artery. This therapy is especially useful in cases of severe proximal and distal CV [16, 18, 19, 20, 21, 22]. However, vessel wall dissection, catheter dislocation, thromboemboli and sepsis due to indwelling foreign material are risks which should be kept in mind (Figure 4). Aggressive measures to prevent thromboembolism should be undertaken which in turn could pose a problem in patients with severe SAH. At our institution, we usually give patients heparin and aspirin and routinely perform a Multiplate test (Roche, Basel, Switzerland) in each patient to exclude any unresponsiveness.

With a session-wise treatment strategy the delayed response to vasodilator infusion should be kept in mind before evaluating the therapeutic response and adjusting the drug dosage. Feng et al. demonstrated angiographic improvement when performing a control angiogram 10-15 minutes after treatment [14].

TRANSLUMINAL BALLOON ANGIOPLASTY (TBA)

TBA for CV is documented thoroughly in the literature [1, 3, 4, 5, 6, 7, 24, 25, 26, 27, 28]. TBA is currently performed with commercially available single and double-lumen over the wire balloon catheters. As with IAIT, TBA has never been investigated in a randomised controlled trial. Uncontrolled clinical case series have demonstrated its safety and technical efficacy, however. The technical efficacy of TBA for reversing CV ranges between 80% and 100%. Clinical success varies considerably, with reversal of DCI in 31% to 77% of patients [6, 7, 24, 25, 26, 27, 28]. Early treatment within 2 h from symptom onset makes a significant positive contribution toward clinical improvement.

When a balloon is inflated in the lumen of a spastic artery, it stretches and disrupts both the already contracted and degenerated muscle and the proliferative non-muscular components, mainly in the tunica media. It paralyses the vessel wall. Thus, the therapeutic effects of TBA are generally long-lasting and retreatment is rarely necessary.

Many experts believe that an expanding balloon in a non-contracted vessel lumen would not achieve the same therapeutic effect. Therefore, many neurointerventionists choose to perform TBA before the initiation of IAIT when combined therapy is planned. With respect to catheterisation and introduction of a balloon catheter, however, it is sometimes necessary to prepare the target vessel with IAIT before TBA.

TBA has been graded as a Class IIb treatment with evidence level B according to guidelines published by the AHA and ASA [1].

SPECIFIC CONSIDERATIONS REGARDING TBA

TBA is usually limited to the proximal vessels of the circle of Willis with diameters greater than 2 mm. Distal balloon angioplasty is generally not recommended. Despite the recent advances in microcatheter technology, tortuous vessels and angioplasty of the anterior cerebral artery still remain technically challenging.

The rate of major complications is approx. 5%. TBA-related complications are vessel rupture, occlusion, dissection, distal embolism, reperfusion injury, displacement of surgical clips and rebleeding from uncontrolled aneurysms.

Prior to TBA, the anatomy of the target vessel before the spasm should be carefully reviewed in order to avoid overdilatation. In the absence of a baseline angiogram, it is often difficult to estimate the normal calibre of a spastic artery and dilatation of a hypoplastic or fenestrated artery may sometimes be encountered. This can be avoided by carefully scrutinising the available angiographic studies. When inflating the balloon, undersizing it to about 80% of the normal vessel diameter is advised. If planning multiple dilatations on a vessel, it is prudent to start distally and continue proximally in order to avoid crossing a fresh angioplasty site with the endovascular material (Figure 5). To avoid multiple dilatations, the balloon length should if possible correspond to the longest straight segment of the target vessel.

TBA is generally contraindicated if the patient has already developed a large infarction in the territory of the target vessel. The same principles of endovascular treatment for acute ischaemic stroke can be applied here. Attempts to restore tissue perfusion to a large infarcted area would increase the risk of reperfusion haemorrhage. Fatal cases of reperfusion haemorrhage have indeed been reported to occur up to 24 h after treating CV with TBA [29].

It is inadvisable to perform TBA adjacent to clipped ruptured aneurysms given that it has been associated with fatal rupture of the parent artery.

(D)

Figure 5. (Continued).

Figure 5. Severe CV of the proximal intracranial arteries (A). TBA performed from distal (C) to proximal. The inflated balloon can be seen (arrows on B and D). Control scan demonstrates good filling of the proximal MCA (E).

Permanent occlusion of the artery, endothelial injury inflicted by the balloon and other standard factors associated with any endovascular intervention mean that appropriate anticoagulation is necessary. Usually, bolus infusion of heparin at the beginning of the procedure followed by repeat doses according to the ACT level should suffice.

Although uncommon, vasospasm may also recur after angioplasty.

BRIEF DISCUSSION AND WRAP-UP

The endovascular therapy of CV consists of two different treatment modalities which can either be used separately or in a complementary fashion. IAIT procedures are generally used in the management of CV involving the distal arteries beyond the circle of Willis, whereas TBA is the treatment of choice for CV of the larger vessels.

IA administration of vasodilating drugs can be safely undertaken in awake patients. On the other hand, most interventionalists prefer to perform TBA on patients under general anaesthesia, because paralysis potentially lowers the risks of the procedure and offers better visibility of the balloon.

In cases of high-grade SAH and delayed presentation to the hospital, CV will often be encountered. If endovascular treatment is planned in such cases, CV can be managed in the same session with aneurysm embolisation [11, 30].

Chapter 75

CHRONIC HYDROCEPHALUS AFTER SUBARACHNOID HAEMORRHAGE

Alexandra Huthmann* and Christoph A. Tschan†

Department of Neurosurgery, Ludmillenstift Meppen, Meppen, Germany

ABSTRACT

Subarachnoid haemorrhage (SAH) causes acute and chronic hydrocephalus. Treatment strategies and alternatives are described from clinical point of view. Modern therapy strategies of chronic hydrocephalus in SAH will be discussed. Treatment methods and modern strategies in daily clinical routine for acute and chronic hydrocephalus in SAH are demonstrated. Ventricular drainage, lumbar drainage, endoscopic third ventriculostomy, intraventricular fibrinolysis and different shunting procedures are focused. Ventricular drainage is gold standard for treatment of acute hydrocephalus in SAH. Additional or exchange to lumbar drainage is discussed to prevent cerebral vasospasm and chronic hydrocephalus. In case of chronic hydrocephalus ventriculoperitoneal shunting is necessary. Different shunt types and valves are available. To prevent overdrainage, a gravitational valve can be added to the differential pressure valve. Adjustable shunt valves allow optimizing pressure level and individual needs. In SAH early CSF drainage can avoid chronic hydrocephalus. Early lumbar drainage may reduce onset of cerebral vasospasm. In case of ventriculoperitoneal shunting adjustable differential pressure valves are effective. The combination with gravitational valves prevents overdrainage.

Keywords: SAH, ventricular drain, lumbar drain, ventriculoperitoneal shunt, gravitational valve, chronic hydrocephalus

The occurrence of disturbances in the circulation of cerebrospinal fluids (CSF) takes two forms: acute and chronic hydrocephalus [1]. The latter will be discussed in this chapter since the acute hydrocephalus was discussed in chapter nine.

The initial therapy of disturbances in the circulation of CSF after subarachnoid haemorrhage is often managed by placement of an external ventricular drainage to manipulate the amount of CSF within the ventricular system. For this procedure a frontal burr hole is placed in order to insert a draining catheter into the anterior horn of the lateral ventricle [2, 3, 4]. In most cases a silicon catheter with a perforated tip is used. Within several minutes after insertion, physiological levels of intracranial pressure can be achieved by this measure; often pressure relief is necessary to achieve optimal conditions for potential aneurysm treatment. An alternative to a silicon catheter is a steel needle (Duisburger Needle) that is introduced through a pre-inserted bolt [5]. In the absence of occlusions in the cerebrospinal fluid circulation, single or repeated lumbar punctures or placement of a lumbar silicon catheter (lumbar drainage, LD) [6, 7] for continuous CSF drainage can be performed. Furthermore the removal of blood from subarachnoid space with a lumbar drainage (LD) may decrease development of cerebral vasospasm [8, 9, 10, 11]. In both cases (ventricular drainage, LD) the silicon catheter will be connected to a sealed draining system (Figure1) [3]. According to the principles of communicating tubes and containers, the amount of cerebrospinal fluid drained, and consequently the intracranial pressure may be adjusted by manipulating the height of the drainage system relatively to the head, or more specific to the ventricles [12]. In our hospital we set up the pressure level of the container 10 cm above the foramen Monroi level (approximately the level of the external auditory canal). Monitoring of the CSF outflow should be documented and in case of over or underdrainage pressure level needs to be readjusted. Maximum outflow in adults should be round about 200 ml in 24 hours.

Figure 1. Sealed draining systems for ventricular and lumbar drain.

The ventricular drain allows ICP monitoring. For this a Statham reservoir (pressure measurement chamber e.g., same system for blood pressure monitoring) has to be added to the system. In some systems the measure unit is integrated. To measure the correct ICP, the

drain has to be closed for a while in front of the container. Measurement in open systems or in case of overdrainage (slit ventricles) reveals wrong ICP values.

In case of severe intraventricular bleeding the drain can be occluded by clots. Sterile flushing is possible. Up to now there is no clear evidence for reducing the risk of chronic hydrocephalus development by using intraventricular fibrinolysis [13, 14].

Chronic hydrocephalus has an incidence of 25% to 37% [15, 16]. Unfortunately, the functionality of CSF circulation is not always restored with the resorption of subarachnoid blood. Additionally, it is quite difficult to identify a potential chronic hydrocephalus in progress by merely evaluating the imaging diagnostics while the drainage system is in function. One way to tackle this issue is by constant clinical and radiographic evaluation of the patient during gradual reduction of the CSF flow rate and subsequent removal of the catheter [17, 18, 19, 20, 21].

If follow up CT- or MRI-scans of the patient show an enlargement of the ventricular system with corresponding clinical deterioration, indicating a potential development of chronic hydrocephalus, a long-term treatment is indicated. A significantly higher rate for need of shunt-therapy was observed in older patients (> 65 years), poor initial neurological status and additional intraventricular haemorrhage [22, 23, 24].

CSF IL-6 values of $\geq 10,000$ pg/ml in the early post-SAH period and assessment of S100B levels in CSF and serum may be useful as predictive parameters for shunt dependency in patients with hydrocephalus following aneurysmal SAH [25, 26].

The long-term treatment is commonly carried out by implantation of a ventriculoperitoneal shunt system (VP-shunt) [27]. Also the use of lamina terminalis fenestration and endoscopic third ventriculostomy is discussed, but both procedures remain to be of limited efficacy. Maybe ETV can be employed as a temporary intervention in certain conditions, such as during the waiting period for the clearance of CSF before inserting a VP-shunt or to treat an obstructive hydrocephalus in case of an additional intraventricular haemorrhage [28, 29, 30].

In our clinical routine CSF protein and cell count are used to decide the right moment for implantation of a VP-Shunt. CSF-Protein should be less than 1g to avoid valve obstruction and CSF samples should count less than 50 cells per μl and no microbiological activity. The objective of the VP-shunt is to connect the ventricles with the peritoneal cavity (subcutaneously) to avoid excessive CSF accumulation in the ventricular system by draining according to the differential pressure gradient between the ventricle and the tip of the distal catheter.

Similar to the technique of implanting an external ventricular drainage, a common method to perform this task is to insert a silicon catheter with a multi-perforated proximal tip in one of the lateral ventricles (usually the right ventricle) through a frontal burr hole. This is connected within a few centimetres with a CSF-reservoir (Control Reservoir) and (a) pressure controlling valve(s). These parts are connected in turn with a distal silicon catheter that ends in the peritoneal cavity through subcutaneous tunnelling [31, 32].

The function of the CSF-reservoir (with unidirectional pump function) is to control the shunt's functionality and to access the CSF circulation if needed. To optimize the flow rate of the CSF, avoiding over- or underdrainage, adjustable differential pressure (DP) valves are used [33, 34, 35].

Figure 2. X-ray of the skull with implanted Miethke proSA[®]-Shunt system with upstream CSF Control-Reservoir, programmable differential pressure valve and programmable gravitational valve (Christoph Miethke GmbH & Co. KG, Aesculap AG, Germany) and telemetric ICP-probe (NEUROVENT[®]-P-tel, RAUMEDIC AG, Germany)

A common problem that mostly occurs during mobilization of shunted patients is overdrainage of CSF, which is poorly controlled by the DP valve. This led to the development of additional gravitational valves (Figure 2) that control flow in the upright position, eventually optimizing CSF flow in various postures, accounting for diurnal variations [36, 37, 38, 39]. Typical signs and symptoms of overdrainage include postural headaches in the upright position that are alleviated by lying down. A typical finding in radiographic scans of the brain (e.g., CT, MRI) is a pronounced reduction in the size of the ventricles (slit ventricles) or subdural hygroma.

Hydrocephalus might take weeks or even months after an instance of SAH to manifest itself, which is why a long-term intensive follow up of such patients is crucial [40, 41, 42]. For this reason diagnostic telemetric ICP-measurement and long-term monitoring are useful especially in difficult cases [43, 44].

Chapter 76

EPILEPTIC SEIZURES IN ASSOCIATION WITH SPONTANEOUS SUBARACHNOID HAEMORRHAGE

Sarah Jesse

Department of Neurology, University of Ulm, Oberer Eselsberg, Ulm, Germany

ABSTRACT

Epileptic tonic-clonic seizures in relation to spontaneous subarachnoid haemorrhage (SAH) should be classified into initial seizures within the first 24 h after SAH, early seizures during the first 14 days, and late onset then with symptomatic epilepsy, given that the therapeutic approach and prognosis are correlated to such clinical stratification. Since randomised controlled and double-blind clinical trials into the management of epileptic seizures with SAH are lacking, therapeutic recommendations can only be made based on the guidance of the Neurocritical Care Society and American Stroke Association.

Initial seizures related to the manifestation of bleeding occur in up to 21%. Anticonvulsant medication should be administered until treatment of the aneurysm, albeit for a maximum of three days, preferably with non-enzyme inducers so as to avoid drug interactions with nimodipine. The incidence of early seizures within the following 14 days does not appear to differ between patients undergoing surgery and those receiving endovascular treatment for ruptured aneurysms (10%-11%). If there are risk factors, such as multiple epileptic seizures or the existence of parenchymal defects, drug therapy should be administered for 3-6 months. The late onset of epileptic seizures post SAH accounts for 12% of the patient population and should, as with any symptomatic form of epilepsy, be managed long-term with anticonvulsants. Non-convulsive seizures and non-convulsive status epilepticus occur in 18% and 13% of cases, respectively, and should be considered in particular in quantitative disorders of consciousness as well as diagnosed with the help of an EEG.

After neurovascular events, epilepsy – with a prevalence of 0.5%-1% – is the second most commonly occurring neurological disorder. It has an incidence of 46 in 100,000 per year and increases with age, and mostly results from symptomatic conditions such as intracerebral/subarachnoid bleeding, ischaemia or neoplasias. Irrespective of whether epilepsy

has been diagnosed, the lifetime prevalence in terms of a single epileptic seizure occurring in the normal population is $> 10\%$ [1].

In relation to spontaneous subarachnoid haemorrhage (SAH), (simple or complex) partial epileptic seizures generally occur, often with secondary generalisation. It is useful to differentiate between initial seizures within the first 24 h after SAH, early seizures during the first 14 days, and late onset then with symptomatic epilepsy, given that the therapeutic approach and prognosis are correlated to such clinical stratification.

INITIAL SEIZURE

In patients with SAH, 3%-21% initially exhibit tonic-clonic seizures at onset or within the first 24 hours of bleeding [2, 3], often if the patient is younger [4] as well as with a higher Fisher score, accompanied by localised cisternal, intraventricular or intraparenchymal bleeds [5]. The occurrence of these initial seizures is associated with a complicated stay in hospital and is often accompanied by further epileptic attacks, an increased rate of pneumonia, and delayed onset of cerebral ischaemia related to vasospasm [6]. Despite the higher risk of complications, the long-term prognosis of the patient does not appear to be adversely affected, particularly as after six months the functional outcome is no worse, mortality is not increased and the prevalence of epilepsy is no higher in those affected [6, 7]. Prophylactic anticonvulsant therapy at this stage is hotly debated, but would seem reasonable for spanning the period until treatment of the aneurysm [8] in light of the fact that the risk of rebleeding is known to be closely correlated with increased systolic blood pressure. Thus, further convulsive epileptic seizures in relation to an untreated aneurysm signify an indirect risk of secondary bleeding [9, 10], which itself is associated with a clinical outcome that is far worse [11]. As systematic studies into anticonvulsive therapy in this regard are still awaited, it is advisable – as recommended by the Guidelines of the Neurocritical Care Society and the American Stroke Association – to administer prophylactic drug therapy during the immediate posthaemorrhagic phase until surgical or endovascular treatment is carried out, albeit for a maximum of three days [12, 13].

EARLY SEIZURE

Epileptic seizures occurring within 14 days after the manifestation of SAH are referred to as early seizures. Data in the literature on ruptured aneurysms are inconsistent with respect to the periprocedural occurrence of epileptic seizures, which are reported at a rate of 13.6% and 8.3% for clipping versus coiling, respectively [14]; this relatively high incidence decreases over the subsequent five years to 9.6% and 6.4%, respectively. In this case younger age as well as a high Fischer or Hunt and Hess score, or delayed ischaemic complications, are also major risk factors/predictors for epilepsy [14, 15]. Contrary to these results, an international study in a total of more than 20,000 patients with spontaneous SAH detected no relevant difference as regards the occurrence of early seizures or epilepsy (10.0% versus 11.1%) between operation and intervention [16].

Postoperative prophylactic drug therapy is frequently administered despite the absence of prior epileptic seizures, but is also hotly debated in the light of recent study data. Randomised controlled trials into the safety and efficacy of anticonvulsant drugs for primary and secondary prophylaxis post SAH are lacking [17, 18]. Moreover, there are studies that have demonstrated an inferior outcome in those patients treated prophylactically with anticonvulsants [19, 20]. The literature available on this topic primarily addresses the use of phenytoin, and in rarer cases carbamazepine and phenobarbital. Apart from the typical side effects of the individual anticonvulsants in the treated populations, an increased number of neurological deficits was detected in particular on account of the higher incidence of ischaemia, possibly owing to the interaction between the given enzyme inducers and coadministration of nimodipine. Its plasma concentration is reduced by up to 70% due to induction of cytochrome p450 [21]. Few studies are available on levetiracetam, which compared to phenytoin does not trigger enzyme production; no difference in the outcome has been noted [22, 23], whilst tolerability with respect to side effects is improved overall [24].

In line with the recommendations of the Neurocritical Care Society (Guidelines 2011) and American Stroke Association (Guidelines 2012), therefore, it is in principle advisable to forgo prophylactic anticonvulsant therapy during the postoperative phase if there are no signs indicative of epileptic seizures. Administration of drug therapy for 3-6 months for early seizures, in the same way as for cerebral ischaemia, appears to be justified [25, 26] if epileptic seizures have already occurred and if, in particular, parenchymal damage has resulted from the SAH or secondary ischaemia [12, 13, 27, 28].

LATE SEIZURE

The long-term incidence of symptomatic epilepsy after spontaneous SAH is 8% during the first year post haemorrhage, and 12% during the subsequent five years. The probability of epilepsy occurring is associated with higher Hunt and Hess grades and with parenchymal damage [29, 30]. Additional risk factors appear to be early epileptic seizures [31] as well as a lower rating on the Glasgow Outcome Scale at hospital discharge [32]. With late-onset seizures carrying a higher risk of recurrence and usually being correlated with a parenchymal defect, a patient should be assumed to have symptomatic epilepsy that will then require treatment in accordance with the guidelines of the ILAE [1].

NON-CONVULSIVE SEIZURE

Non-convulsive seizures occur in 8%-18% of patients [33]. A number of studies that performed continuous EEG monitoring in SAH patients revealed an incidence of up to 18% for complex partial non-convulsive seizures and up to 13% for non-convulsive status epilepticus, which was associated with the increased age of the patients as well as higher mortality. Furthermore, delayed cerebral ischaemia could be predicted in one study based on specific EEG changes (reduced delta/alpha ratio, relative alpha variability and amplitude) [34]. As continuous EEG monitoring is not practicable in clinical routine, it certainly will not replace regular Doppler ultrasound in the detection of vasospasms. However, in patients with

persistent disorders of consciousness – whether in terms of quantity or quality – an EEG should be performed to rule out non-convulsive seizures or non-convulsive status epilepticus.

Epileptic activity as a differential diagnosis in localised subarachnoid signal alterations on CT and MRI.

Both computed tomography (as the “gold standard” for early diagnosis of SAH) and magnetic resonance imaging permit detection of signal alterations in the subarachnoid space which in addition to SAH are also attributable on differential diagnosis to other conditions, such as an inflammatory exudate in meningitis, meningeal spread, hypertension-induced exudate associated with posterior reversible encephalopathy syndrome, cerebral amyloid angiopathy, cortical venous thrombosis or vascular malformation [35]. Further differential diagnoses include reversible cerebral vasokonstriction syndrome, hyperanticoagulation with vitamin K antagonists, and angiitis [36]. In association with renal failure, localised subarachnoid exudate can also appear on follow-up imaging after administration of a contrast agent [37]. Another important factor to be considered in the differential diagnosis of spontaneous SAH, as well as vasospasm-induced ischaemia, is localised cortical and also subarachnoid signal alteration in the event of protracted or frequent seizures as well as (non-convulsive) status epilepticus [38] (Figure1).

Figure 1. CT and MRI scans from a female patient with non-convulsive status epilepticus existing for several days. Evidence of localised subarachnoid hyperdensity/hyperintensity in the left upper frontal lobe consistent with protein-rich exudate. Courtesy of the Neuroradiological Department of Neurology, Rehabilitation Hospital Ulm, Ulm, Germany.

Summary of the major aspects of epileptic seizures in spontaneous SAH:

- Stratification of epileptic seizures into initial, early and late is reasonable given that treatment and prognosis are designed with these categories in mind.
- Since randomised controlled and double-blind clinical trials into the management of epileptic seizures with SAH are lacking, therapeutic recommendations can only be made based on the guidance of the Neurocritical Care Society and American Stroke Association.
- Initial cases related to the manifestation of bleeding occur in up to 21% of SAH cases and are associated with a complex hospital stay. Anticonvulsant medication should

be administered until treatment of the aneurysm, albeit for a maximum of three days, preferably with non-enzyme inducers so as to avoid drug interactions with nimodipine.

- The incidence of early seizures within the following 14 days does not appear to differ between patients undergoing surgery and those receiving endovascular treatment for ruptured aneurysms (10%-11%). If there are risk factors, such as multiple epileptic seizures or the existence of parenchymal defects, drug therapy should be administered for 3-6 months.
- The late onset of epileptic seizures post SAH accounts for 12% of the patient population and should, as with any symptomatic form of epilepsy, be managed long-term with anticonvulsants.
- Non-convulsive seizures and non-convulsive status epilepticus occur in 18% and 13% of cases, respectively, and should be considered in particular in quantitative disorders of consciousness as well as diagnosed with the help of an EEG.
- Subarachnoid signal alterations on CT and MRI can be indicative not only of SAH but also of other conditions, such as a protracted epileptic seizure or (non-convulsive) status epilepticus, and should be considered when deliberating the differential diagnosis.

Chapter 77

NEUROREHABILITATION AFTER SUBARACHNOID HAEMORRHAGE

Martin Schorl and Michael Hartwich

Early Neurological/Neurosurgical Rehabilitation,
Asklepios Schlossbergklinik Bad König, Frankfurter Strasse 33,
Bad König, Germany

ABSTRACT

Neurorehabilitation after subarachnoid haemorrhage (SAH) is of major importance in all patients surviving the acute stage of their illness but remaining disabled. Neurorehabilitation aims at regaining self control in the activities of daily living in severely affected patients or the return to the workplace in moderate affected patients.

This chapter describes the German Phase model for neurorehabilitation after central nervous damage in general and focuses on the patients severely affected after SAH. Severely affected patients after central nervous system damage are treated by early neurological and neurosurgical rehabilitation as the link between acute care and rehabilitation. Early neurological and neurosurgical rehabilitation becomes increasingly specialized, nowadays integrating intensive care treatment modalities and rehabilitation. The aim was to minimise the need to return patients from early rehabilitation back to the emergency department and facilitate integrated rehabilitation treatment with accompanying treatment of the typical complications. For this to happen, a combination of multidisciplinary emergency and rehabilitative measures are usually needed which, depending on the respective medical situation, can be carried out in varying degrees of intensity and dominance.

The interdisciplinary approach of early neurological and neurosurgical rehabilitation is discussed in detail concerning the characteristics of the patients treated, the setting, the multidisciplinary treatment concept including the medical and therapeutic staff and the diagnostic equipment required.

Special aspects of neurorehabilitation after SAH are discussed in detail. Data concerning outcome are presented. Overall, they show the benefit of early neurological and neurosurgical rehabilitation both from the patient's and the society's perspective.

Keywords: neurorehabilitation, German phase model of neurorehabilitation, early neurological rehabilitation, early neurosurgical rehabilitation, interdisciplinary neurorehabilitation

DEVELOPMENT OF NEUROREHABILITATION AND LEGAL REGULATIONS

Early rehabilitation after stroke has proven superior to late rehabilitation [20]. Rehabilitation should therefore be commenced at the earliest opportunity in the acute phase during initial treatment so as to increase the chances of rehabilitation and not to lose any valuable time [4]. Since 2001, therefore, social law in Germany has included an entitlement to rehabilitation services during acute inpatient care (Section 27 of Social Security Code (SGB) IX).

However, the phase model for the rehabilitation of individuals with severe and very severe brain damage was inaugurated as early as 1995 by the Bundesarbeitsgemeinschaft Rehabilitation (BAR) [Federal Rehabilitation Council] [4]. The Bundesarbeitsgemeinschaft Rehabilitation is an amalgamation of different health insurance providers (umbrella organisations for health insurance, accident insurance, annuity insurance) with the participation of the Medical Review Board of the Statutory Health Insurance Funds, representatives of the federal states, medical societies and medical experts.

The aim of the phase model was to create an integrated treatment and rehabilitation chain targeted to the needs of patients and accounting for both medical and rehabilitative requirements.

**Table 1. Phase model for neurorehabilitation of individuals
with severe brain injury in Germany**

Phase	Definition
A	Acute care including surgery, neurosurgery, interventional neuroradiology, neurointensive care.
B	Early post-acute rehabilitation treatment; intensive care facilities must be provided, may include mechanical ventilation.
C	Continuing rehabilitation. Vital signs are stable and the patient is able to participate actively in therapy, but requires some medical care. Partly dependent in activities of daily living (ADL).
D	Follow-up rehabilitation. Patients are mostly independent in ADL; medical therapies aimed at returning to work, may be performed on an outpatient rehabilitation basis.
E	Occupational retraining or reintegration.
F	Function-preserving nursing care and therapies for patients with disorders of consciousness or persistent, severe disabilities (e.g., occupational therapy, physiotherapy, oral tract therapy), either in specialized nursing homes or at home, sometimes with home ventilation therapy.

In this phase model, a distinction is made (Table 1) between an acute phase and several subsequent rehabilitation phases: ideally, once primary acute hospital treatment (Phase A) is complete, the patient initially receives care under Phase B (known as “early neurological rehabilitation”), then Phase C (continuing rehabilitation), and finally Phase D (follow-up rehabilitation). One or more of the above-mentioned phases can be skipped depending on the level of care required by the patient or the degree of independence achieved.

Occupational reintegration or retraining can take place in Phase E. If after early rehabilitation (Phase B) the level of independence is not sufficient to move on to the subsequent rehabilitation phases, out-of-hospital nursing care is introduced while continuing with the treatment programme (Phase F). The aim here is to at least maintain the level that has been achieved and avoid secondary complications.

With the introduction of a new hospital billing system (G-DRG) in 2001, early neurological rehabilitation is now predominantly funded through flat rates per case, which are based on the one hand on medical diagnoses and on the other hand on reimbursement-relevant procedures. The complex flat rate for “early neurological rehabilitation” (known as OPS 8-552) [7] can only be billed if certain qualitative structural and quantitative requirements are fulfilled. Therefore, among other things, at least 300 treatment minutes per patient per day must be provided and weekly team meetings with standardised assessments carried out.

In contrast to developments in other countries, where rehabilitation teams attend to severely affected patients during anaesthesiological and neurological/neurosurgical treatment (outreach rehabilitation), specialist clinics have been established in Germany that have the necessary medical and rehabilitative expertise along with the staff and equipment required to also deal with patients in critical condition who are still in need of intensive care immediately after undergoing emergency treatment. This enables rehabilitative approaches to be integrated into the treatment programme at the earliest opportunity.

As a result of neurorehabilitation becoming increasingly specialised in its position as the link between the acute disciplines of neurology and neurosurgery as well as rehabilitation, attempts have been made to introduce an additional qualification in neurorehabilitation or the separate title of specialist for neurorehabilitation into basic and advanced training. Relevant initiatives are also afoot internationally within the framework of the European Federation for NeuroRehabilitation (EFNR).

EARLY NEUROLOGICAL REHABILITATION/PHASE B ACCORDING TO THE PHASE MODEL

General Aspects

Patients

Among all patients in early neurological and neurosurgical rehabilitation, patients post subarachnoid haemorrhage (SAH) account for 7.5% to 28% [9, 12, 18] of total patient numbers depending on the specialisation of the hospital.

Patients in early neurological and neurosurgical rehabilitation are typically medically unstable over a lengthy period of time and may have a variety of complications ([3], Table 2). On the one hand, these are pre-existing comorbidities involving other organ systems, and on the other hand complications in the central and peripheral nervous system. A distinction is essentially made here between direct nervous system complications (e.g., epilepsy, critical illness polyneuropathy, hydrocephalus, sinking skin flap syndrome after decompressive craniectomy) or the impact of the symptoms of neurological damage on other organ systems (e.g., pneumonia following neurogenic dysphagia, electrolyte imbalance and arrhythmia as a result of central endocrine insufficiencies, intestinal motility disorders with vomiting as a result of autonomous functional disorders of the peripheral nervous system).

Table 2. Typical medical complications in early neurological/neurosurgical rehabilitation

Organ system	Symptom	
Central and peripheral nervous system	Meningitis/ventriculitis	
	Epileptic seizure	
	Convulsive and non-convulsive status epilepticus	
	Critical-illness polyneuropathy	
	Neurogenic dysphagia	
	Malresorptive hydrocephalus	
	Shunt dysfunction, shunt infection	
	Sinking skin flap syndrome	
Endocrine system	Diabetes insipidus	
	Cerebral salt-wasting syndrome	
	Syndrome of inappropriate ADH secretion	
	Electrolyte disorders	
	Acquired anterior pituitary insufficiency	
Vegetative system	Sympathicotonic dysregulation	Tachycardia
		Arterial hypertension
		Hyperhidrosis
		Tachypnoea
		Hyperthermia
	Gastrointestinal dysregulation	Vomiting
		Pylorospasm
		Reflux
		Diarrhoea
Cardiopulmonary system	Cardiac arrhythmias	
	Heart failure	
	Endocarditis	
	Takotsubo cardiomyopathy	
	Pneumonia	
	Bronchial obstruction	
	Thrombosis, pulmonary embolism	
	Pneumothorax	
	Pleural effusion	
	Pleuritis	
Gastrointestinal system	Gallstones, gallbladder sludge	
	Cholestasis	
	Cholecystitis	
	Hyperammonaemia	
	Gastritis, ventricular ulcer, duodenal ulcer	
	Ascites	
	Peritonitis	
Genitourinary system	Urinary tract infection	
	Renal failure	
	Nephrolithiasis	
	Haematuria	
	Incontinence	
Musculoskeletal system	Heterotopic ossification	
Bacteria requiring isolation	MRSA, 3-MRGN, 4-MRGN, clostridia, VRE	
Pre-existing diseases	Cancer	
	Coronary heart disease	
	Bronchial asthma	
	Mental illnesses	

Organ system	Symptom
	Infectious diseases (hepatitis, HIV)
	Parkinson's disease, Parkinson's syndrome, multiple sclerosis
	Inflammatory bowel diseases
Medication	Sedative effects (e.g., antidepressants, antiepileptics)
	Interactions
	Proconvulsive effects (e.g., theophylline, anti-infectives, activating substances)

The BAR defined the task of early rehabilitation, among other things, as “the medical diagnosis and curative medical treatment of underlying diseases and comorbidities from neurological damage” [4, point 3.1.3., page 10] and mentioned explicitly that “management of life-threatening complications and any complications occurring during mobilisation must be possible” [4, point 3.1.3., page 10].

The aim was thus to minimise the need to return patients from early rehabilitation back to the emergency department and facilitate integrated rehabilitation treatment with accompanying treatment of the typical complications. For this to happen, a combination of multidisciplinary emergency and rehabilitative measures are usually needed which, depending on the respective medical situation, can be carried out in varying degrees of intensity and dominance. Significant overarching tasks in early neurological and neurosurgical rehabilitation involve the continuation of the curative medical efforts initiated as part of acute treatment, support in the remission of CNS/PNS damage by promoting neuroplasticity (basal objectives: improved vigilance, cooperation, ability to communicate), implementation of compensatory and adaptive measures that reduce the need for assistance and increase quality of life, evaluation of the potential for rehabilitation, and the organisation of further care [3]. Ideally, patients can be transferred to continuing rehabilitation phases (Phase C) if there is a corresponding improvement in independence.

Nowadays, patients are transferred to early neurological and neurosurgical rehabilitation immediately on completion of neurological, neurosurgical, or interventional neuroradiological acute medical care. At such a time, many patients are still under analgosedation and mechanical ventilation, and often still have cerebrospinal fluid drains in situ. Medically speaking, the main objectives at this early phase are medical stabilisation, weaning from ventilation, tapering off the analgosedation and achieving an adequate rehabilitative capacity. Initial, mostly passive rehabilitation measures run parallel to this. Ideally, as treatment progresses, intensive care takes a back seat in favour of rehabilitation that takes an increasingly active approach.

To this end, drugs that influence the level of consciousness and stabilise the circulation must be tapered off. As vigilance improves, sympatheticotonic dysregulation of the autonomic nervous system often comes to the fore which, given the tendency for tachycardia and hypertension to develop, can be detrimental to early mobilisation and, as a result of hyperhidrosis, can lead to fluid losses and electrolyte imbalances. Nursing care (e.g., from the concept of basal stimulation) and positioning concepts are incorporated in the multidisciplinary approach alongside drug therapies. To make patient mobilisation easier, formulations of substances administered via enteral feeding tube are to be preferred for drug treatment in contrast to substances requiring intravenous application. As a result, changes in medication must also be undertaken frequently during the initial phase.

In the event of severe damage to the central nervous system, or as a result of critical illness polyneuropathy often occurring as a complication in up to 69% [27], there is often evidence of neurogenic dysphagia. After appropriate diagnostic testing, usually involving endoscopy, this will necessitate the insertion, at least temporarily, of a tracheostoma for protection against aspiration as well as percutaneous feeding tubes. The improvement in swallowing function with the aim of decannulation in the tracheotomised patient is also one of the primary objectives of early neurological rehabilitation, which is why swallowing rehabilitation is initiated as a multidisciplinary approach from the time of admission onwards.

Setting

Appropriate equipment and staffing are indispensable to the above-mentioned diagnostic and therapeutic activities, as an accompaniment to intensive care treatment, if the patient is not to be subjected to the stresses of being transferred. The aim is to offer patients “one-stop” care. Otherwise, rehabilitation would in the worst-case scenario be repeatedly interrupted. Early neurological and neurosurgical rehabilitation is therefore carried out predominantly in specially dedicated clinics that in some cases also offer subsequent rehabilitation phases (see below), more rarely as a functional facility affiliated with acute hospitals. Early neurological and neurosurgical rehabilitation is to a large extent characterised by interdisciplinarity – not only from a medical point of view, but also from the perspective of nursing and therapy.

Multidisciplinary Treatment Concept

Early neurological and neurosurgical rehabilitation is carried out under the supervision of a neurologist and/or neurosurgeon with at least three years of experience in neurorehabilitation. Depending on (intensive care) orientation and equipment, as well as the available diagnostic and therapeutic services, the medical team usually consists not only of neurologists, but also physicians, general practitioners, rehabilitation and intensive care specialists. Since transfers to neurosurgery constitute the second most frequent type of transfer alongside transfers to internal medicine [30], some facilities do now employ neurosurgeons or collaborate with neurosurgical clinics in order to offer elective secondary surgical procedures in-house alongside rehabilitation. Expertise in neuroradiology is usually provided via links with (neuro) radiology practices or centres, where teleradiological concepts are increasingly ensuring widespread availability and results of high quality.

Care staff receive basic and advanced training both in intensive care and neurorehabilitation. This combination is of particular importance since patients should benefit as early as possible from neurorehabilitative nursing while on intensive care, and rehabilitative care has huge significance in neurorehabilitation beyond basic care and treatment. This results primarily from the fact that in severely affected patients a number of rehabilitative aspects are viewed within the context of activities of daily living. Catalogues of nursing services have been defined on this basis [11].

The primary objective in physiotherapy is initially to achieve early mobilisation and train the circulation with the aim of sufficient cardiopulmonary capacity and stability in the autonomic nervous system in readiness for the subsequent rehabilitation steps. At the early phase, close coordination with the intensive care specialists and the therapists’ own expertise in intensive and respiratory medicine are always essential aspects that can help to interpret the reactions of patients. The purpose of early mobilisation is also to achieve the best possible physiological muscle tone, facilitate first movements, develop targeted motor skills and

incorporate them into activities of daily living, and improve postural control. An essential basis for improving motor skills on the one hand, and achieving progress in terms of dysphagia, level of consciousness and environmental interaction on the other, is verticalisation. Later on in the process of neurorehabilitation, the focus is then on change in position, transfers to a wheelchair, wheelchair locomotion and walking. In the case of very severely affected patients, efforts to influence pathologically affected muscle tone come to the fore.

In many early rehabilitation clinics, the therapeutic focus of occupational therapy is not only on motor rehabilitation of the upper extremities so as to restore the hand motor skills to a sufficient degree in everyday and professional life, but also dysphagia therapy, including tracheal cannula management and the reinstatement of an oral diet. This also requires specialist knowledge in respiratory therapy, instrumental diagnosis of dysphagia and close coordination with other therapeutic areas that frequently complement each other in their approaches to the problem (nursing, speech therapy).

The primary task of neuropsychology in early neurological and neurosurgical rehabilitation is on the one hand to diagnose and assess disorders of consciousness with regard to interpreting basic approaches of interaction and developing early communication methods for and with patients, and on the other hand to diagnose and treat the characteristic neuropsychological symptoms and syndromes. Supporting relatives is also very important, as is the advice and guidance of the therapeutic team in case of patients with mental (e.g., depression with suicidal tendency) or neuropsychological (e.g., organic brain syndrome with restlessness, aggressiveness and behaviour that is harmful to the self or others) disorders. Neuropsychology is often the discipline where first-line diagnosis and treatment of aphasic disorders are undertaken in the process of developing methods of communication.

Besides the diagnosis and treatment of aphasia and dysarthria, which are frequently limited in early neurological rehabilitation by concurrent neurocognitive deficits, the diagnosis and treatment of dysphagia is a further area of expertise covered by speech therapy.

Table 3 provides an overview of the respective treatment modalities.

In addition to these standard therapies, a variety of other treatments (e.g., music therapy, art therapy, animal-assisted therapy, physical therapy) are used in different combinations. Increasingly, modern (e.g., robot-assisted locomotion therapy) and evidence-based (e.g., constrained induced movement therapy) therapies find their way into early rehabilitation, sometimes adapted specifically to the patients.

The complexity of injury patterns in patients on the one hand and the variety of specialist disciplines involved in the treatment on the other hand rely on clear and thorough communication on the part of all those involved, and a flexible approach to planning with targeted selection and implementation of treatment. Regular interdisciplinary team meetings every week are therefore an opportunity to exchange information, focus on objectives and mutually agree on the treatment plan. Multidisciplinary treatment concepts (e.g., botulinum toxin injection into the salivary glands for reducing the amount of saliva in pseudohypersalivation with risk of aspiration following reduced swallowing frequency, thereby facilitating dysphagia therapy and extending tracheal cannula unblocking times) and concurrent programmes from various disciplines (e.g., physiotherapy for mobilisation into a sitting position and speech therapy for managing dysphagia in the achieved sitting position) are characteristic of the early neurological and neurosurgical rehabilitation activities that rely on considerable staff input.

Table 3. Overview of therapeutic treatments in Phase B

Nursing therapy 4-6 hr/d	• Diagnostics: Skin conditions, position tolerance, primary behavior observation, assessment of endurance • Basal stimulation: activating “guided” basic care, initiation of cooperation in mini-sequences in the ADL • Relaxing therapies in agitated phases: bathing, positions, communication, reduction of sedating medication
Physiotherapy 1-2 hr/d	• Diagnostics: muscular tone, joint flexibility, pathological movements • Prophylactic treatment to prevent complications: against contractures, pneumonia • Mobilisation (even if patients are on respiratortherapy): “Pilot”-seat, bed edge, wheel chair, improvement of circulatory endurance, initiation of first position and support reactions • Respiration therapy: assistance in weaning of respirator, secretion control • Multimodal stimulation for improvement of perception • Reduction of pathologically increased muscle tone: functional positioning, modified neurophysiologically orientated treatment procedures, casting • Regain of mobility: transfer and wheelchair training, treadmill training, balance training, walking with and without auxiliary devices
Occupational therapy 1-2 hr/d	• Diagnostics: swallowing function, secretion control, assessment of aspiration risk • Facio-oral tract (FOT) therapy: improvement of swallowing reflex, weaning from tracheal tube after successful weaning from the respirator, management of tracheal tube • Improvement of hand function: Reduction of pathological muscle tone, establishing first and functional movements, expansion of usage in activities of daily living, e.g., constraint induced movement therapy (CIMT), improvement of fine motor skills, reduction of apraxia and ataxia • Training of abilities in activities of daily living: bathing, clothing, eating • Improvement of multimodal perception • Adaption of auxiliary devices • Neurocognitive training: planning strategies, attention, memory
Neuropsychology 2-3 hr/wk	• Diagnostics: assessment of level of consciousness using standardized behavioral observation, scales and screenings • Recommendations for interaction with the patient • Daily scheduling based on endurance • Establishing communication: communication code, communication training • Family counseling
Speech therapy (complementary or as needed)	• Diagnostics: Different types of aphasia, dysarthria, swallowing disorders, evaluation of aspiration risk • Establishing communication communication code, auxiliary devices, communication training, compensation strategies • Facio-oral-tract-(FOT)-therapy • Training and improvement of swallowing and eating, compensation strategies • Management of tracheal tubes
Music therapy (as needed)	• Diagnostics: attempt to create musical contact in cases of severe disturbed consciousness • Establishing communication: relaxing or animating musical stimulation, musical communication code

Specific Aspects in Patients Post Subarachnoid Haemorrhage (SAH)

A few specific aspects must be considered in the neurorehabilitation of patients after SAH. These concern firstly the underlying condition, and secondly the characteristic symptoms and typical additional complications.

With regard to the underlying condition, the extent to which untreated, partially treated or fully treated aneurysms are to be given follow-up treatment and monitored must be agreed specifically with the neurosurgeons or neuroradiologists providing initial treatment. The modern interventional neuroradiological treatment procedures sometimes mean that anticoagulant therapy is necessary. This must be considered with respect to competing comorbidities and planning of the necessary secondary interventions (placement of percutaneous feeding tubes, elective neurosurgical secondary interventions). On the other hand, the anticoagulant therapy required for internal comorbidities can be hampered or prove impossible if the placement of a cerebrospinal fluid drain has to be performed repeatedly. As a result of the often early transfer of patients to early neurological and neurosurgical rehabilitation, vasospasm therapy or prophylaxis is also occasionally shifted to early rehabilitation, meaning that appropriate expertise and options for instrumental diagnosis must be available.

As occlusive hydrocephalus is initially common, and communicating hydrocephalus is not uncommon over the course, particularly in severe SAH, the diagnosis of hydrocephalus and indication for shunt placement is the preserve of early neurological and neurosurgical rehabilitation and must be closely coordinated with the neurosurgeon. Frequently, these patients are also transferred to early neurological and neurosurgical rehabilitation with cerebrospinal fluid drains still in situ. Handling these drains and weaning are also typically the responsibility of early rehabilitation.

The identification of absolute (e.g., occlusion) or relative (incorrect valve setting) shunt dysfunction in patients with implanted shunts is another issue to be managed as part of neurorehabilitative treatment. Clinically, these patients can usually only be assessed inadequately with regard to shunt dysfunction, as the symptoms of shunt dysfunction and primary damage overlap [5], are frequently only subtle, and merely cause the course of rehabilitation to stagnate [5]. Imaging procedures do not often sufficiently distinguish between shunt dysfunction and the consequences of the primary damage [5]. In recent years, there has been increased use of a gravitational unit ("shunt assistant") combined with the shunt valve as a means of preventing overdrainage when the body is in the upright position. However, in patients who are predominantly bedridden they can lead to a relative shunt dysfunction due to underdrainage [14] and should therefore not be implanted in this patient group.

With the increasing use of decompressive hemicraniectomy as the treatment of last resort in treatment-resistant increased intracranial pressure with accompanying intracerebral haemorrhage and vasospastic infarctions, the diagnosis of a sinking skin flap syndrome [1, 24, 31] that may lastingly impair neurorehabilitation [24] and identification of the need for cranioplasty is very important. After cranioplasty it is essential to promptly diagnose as well as introduce appropriate treatment for complications such as aseptic bone necrosis following autologous cranioplasty with a risk of bone resorption or a sinking bone syndrome [8].

Epileptic seizures are a well-known consequence of focal brain damage. In the differential diagnosis of disorders of consciousness as a result of primary damage, non-

convulsive status is of particular significance. The preferred antiepileptics for treatment of symptomatic epilepsy are those that do not impair consciousness, have as little interaction potential as possible, and can be administered easily via a feeding tube. Given the difficulties of differential diagnosis in the case of disorders of consciousness (e.g., valproate-induced encephalopathy) and the potential of pharmacological interactions with loss of effectiveness (e.g., when administering the antibiotic meropenem, which is frequently used in intensive care), valproic acid should not be used as first-line treatment in these patients, which is in contrast to common therapy guidelines in epilepsy. In our own experience, lacosamide also leads to encephalopathy-type conditions time and again. In patients dependent on tube feeding, phenytoin is obsolete, as an effective drug level cannot be achieved [30, own experience].

Organic brain syndromes (OBS) with pronounced drive disorders are not unusual after SAH due to aneurysms commonly being found in the anterior communicating artery or the A1 and proximal A2 segment of the anterior cerebral artery [2]. Not uncommonly, like other neuropsychological symptoms, OBS are also crucial to the functional outcome [19] and can hinder rehabilitation. With regard to attempts at drug treatment, the differentiation of reactive depression, malresorptive hydrocephalus, a symptomatic sleep apnoea syndrome, endocrine problems and a non-convulsive status from organic brain syndromes with reduced drive is important. In the first instance, drug treatment to improve drive is attempted with amantadine, and also levodopa, drive-stimulating antidepressants, and more rarely with amphetamines. Our experience with modafinil is good, especially with simultaneously impaired vigilance. It is worth remembering that, apart from amantadine, the use of medication is beyond any approved indication and the relevant medicolegal aspects of off-label use should be considered. Amnesic syndromes are hardly accessible with drug therapy and require intensive neuropsychological treatment with development of compensation strategies and if necessary accommodation in a special setting (contained area).

At a rate of 47.5%, endocrine disorders of superordinate hypothalamic-pituitary hormone production occur more frequently after SAH than after traumatic brain injury (27.5%) [21]. Interestingly, the occurrence does not correlate with the severity of the subarachnoid haemorrhage [21]. They more often affect only one endocrine axis in isolation, and less often several at once [22]. Frequency figures fluctuate between 5.4% and 57.5% depending on the test procedures and their timing [22]. An essential problem results from a lack of reliable reference values for endocrine disorders in the early phase following brain damage.

Corticotrophic insufficiency is of particular relevance to early neurological and neurosurgical rehabilitation, as it is aside from somatotrophic insufficiency the most frequent insufficiency [22], often sidesteps routine laboratory tests (compared to thyrotrophic insufficiency), is often difficult to diagnose on a clinical level as a result of the often unspecific or ambiguous symptoms, but in stressful situations (infections, operations) can even result in life-threatening Addisonian crisis. Furthermore, corticotrophic insufficiency is usually only a relative one, with normal or borderline basal cortisol levels. Often, significantly higher substitution doses than usual are needed [26]. Other endocrine disorders in the form of diabetes insipidus (up to 3% [22]), syndrome of inappropriate ADH secretion or cerebral salt-wasting syndrome may occur.

As time goes on, spasticity frequently develops as a consequence of focal brain damage from concurrent bleeding or vasospastic infarctions, or herniation in severely affected patients. This often requires further therapy such as botulinum toxin injections, joint

mobilisation under anaesthetic and corrective cast treatment in addition to the basic measure of physiotherapy. Systemic antispastic agents should preferably be avoided because of frequently occurring cognitive and gastrointestinal side effects with at the same time a mostly inadequate effect on severe spasticity, even at high doses. In contrast, experience with intrathecal baclofen therapy is positive [30; own experience]. Appropriate multimodal therapy in the case of severe spasticity requires, time and again, a combination of all therapeutic aspects and options and is ideally only to be performed in the early neurological and neurosurgical rehabilitation setting.

Critical illness polyneuropathy (CIP) often develops over the further course and is of particular significance in the rehabilitation process. It has additional negative implications in terms of the patient's motor skills, often leads to neurogenic dysphagia, reduces physical resilience and prolongs the process of weaning off ventilation in a highly significant way [27]. Because the symptoms of central nervous and peripheral nervous damage overlap, the clinical diagnosis of CIP in patients post SAH is unreliable [13]. Using a standardised electrophysiological test, the incidence of critical illness polyneuropathy as a concomitant condition was found to be 69% in patients in early neurological and neurosurgical rehabilitation [27].

Haemorrhaging in the vitreous body of the eye (Terson syndrome) is not uncommon after subarachnoid haemorrhage. The reported incidence fluctuates between 12% and 50% [6, 10]. The resulting visual disturbances often have a lasting negative impact on rehabilitation, as they are often recognised only late on in patients whose communication is impaired. Especially in this condition, ocular ultrasound is a simple and safe screening method.

Other complications often emerge at the interface with other medical disciplines (e.g., neurourology in the case of neurogenic bladder disorders, psychiatry in the case of depression, cardiology in the case of stress-induced cardiomyopathy [Takotsubo cardiomyopathy] or unspecific ECG changes, pulmonology in the case of neurogenic pulmonary oedema, gastroenterology in the case of gastrointestinal motility disorders with gastroparesis, reflux and vomiting, infectiology in the case of central fever, etc.).

In addition, complications that develop with other diseases but are not typically associated with SAH can also occur of course during the rehabilitation of SAH patients (Table 2). Given that infections are a frequent complication, clinically-orientated, moderate antibiotic treatment is essential in view of the increasing problem of multidrug-resistant pathogens firstly to adequately treat the infection, and secondly to minimise the selection of multidrug-resistant pathogens. Eradication is often impossible in neurological rehabilitation due to various factors (e.g., long-term placement of cannulae, broad spectrum antibiotics often necessary, multiple antibiotic pre-treatments in long-term intensive therapy and ventilation, incontinence, limited cooperativeness). The necessary isolation limits rehabilitation options, and the chances of successful rehabilitation are therefore reduced. Therefore, in the case of elevated body temperature it is appropriate to differentiate between bacterial infection and a central fever.

Finally, it is worth mentioning that many pharmacological approaches constitute off-label use in accordance with current regulatory provisions. Alongside the increased need for a clear indication, additional information and accurate documentation occasionally off-label use brings with it problems in relation to the reimbursement of the costs for expensive treatments (e.g., botulinum toxin) since health insurers can deny payment in this context.

Outcomes of Early Neurological/Neurosurgical Rehabilitation

The individual federal states are responsible for defining health policy in Germany. Germany-wide data are therefore scarce or can only be compared to a limited extent due to distinctions between the states. To illustrate the outcomes, the data from the Quality Assurance Institute in Hessen and data from our own hospital (also located in Hessen) are presented and compared. With six million inhabitants, Hessen is the fifth largest federal state in Germany. All stroke patients and thus all patients with SAH are registered by the acute hospitals as a compulsory measure with the Hessen Quality Assurance Institute. As early neurological and neurosurgical rehabilitation is also assigned to the acute hospital sector according to social legislation (Section 39 SGB V), comprehensive data are also available on this topic.

In 2013, 487 patients with SAH were admitted to acute hospitals in Hessen. The mean inpatient stay for acute hospital treatment for all patients with SAH was 15.7 days (standard deviation: ± 10.9 days). 259 out of 487 (53.2%) patients were ventilated. The mean duration of ventilation was 13.3 days (standard deviation: ± 12.6 days). Concerning the duration of ventilation it should be noted that some of the patients (especially the more severely affected) were transferred to early neurological and neurosurgical rehabilitation in a ventilated state and therefore were excluded in the above mentioned analysis.

Table 4 illustrates the functional outcome at the end of acute treatment, classified according to the modified Rankin Scale.

Throughout Hessen, 175 out of 487 (35.9%) patients post SAH were transferred to early neurological and neurosurgical rehabilitation. Table 5 compares the relevant characteristics of the patients in Hessen and at our own hospital.

In Germany, the Barthel Index [15] was established as a standard tool for assessing functional independence, although it was originally designed for patients with quadri-/paraplegia and has some methodological weaknesses. Because of the severity of the damage and the resulting lack of independence, patients in early neurological and neurosurgical rehabilitation are not represented by the Barthel Index, or only late on in the course of the disease owing to the so-called floor effect. Therefore, in Germany, the Early Rehabilitation Barthel Index [23] was introduced to illustrate typical early rehabilitation items which better describe the severity of a patient's condition. Improvements in these items are therefore more appropriate than the Barthel Index for elucidating the advances in early rehabilitative treatment (Table 6).

**Table 4. Functional outcome at the end of acute treatment (n = 487)
based on the modified Rankin Scale**

Scale	Definition	Number of patients	%
0	No symptoms	68	14.0
1	Symptoms with no relevant functional impairment	89	18.3
2	Mild functional impairment	30	6.2
3	Moderate functional impairment	39	8.0
4	Moderately severe functional impairment	57	11.7
5	Severe functional impairment	120	24.6
6	Death	84	17.2

* Multiple answers possible, ** discharge vs admission

Length of Acute Hospital Stay (for Patients Transferred to Early Neurological/Neurosurgical Rehabilitation)

The length of stay for primary acute hospital treatment until transfer to early neurological and neurosurgical rehabilitation was 45.7 ± 50.3 days (median 28 days) in Hessen as a whole and 38.2 ± 46.4 days (median 23 days) at our clinic, and thus can be easily compared against an earlier 2005 overview of unselected diseases with a latency of transfer to early neurological and neurosurgical rehabilitation treatment of 47.0 ± 90.2 days (median 27 days) [28]. As this value also includes diseases (cerebral infarction, hypoxia) that are typically associated with shorter acute hospital stays compared to SAH and traumatic brain injury, it can be assumed that the length of acute hospital stay for patients with SAH admitted to early neurological and neurosurgical rehabilitation has slightly decreased in acute medicine in the last ten years.

Percentage of Ventilated Patients Admitted to Early Neurological and Neurosurgical Rehabilitation

The percentage of patients admitted to early neurological and neurosurgical rehabilitation still in a ventilated state (unselected diseases) was 16.6% in 2002 [12] and 18.4% in 2005 [28]. An increase can be established in this regard, as the Hessen-wide percentage of 36.6% among all the SAH patients admitted to early rehabilitation shows (Table 5). The rate at early rehabilitation facilities with a strong intensive care focus is even higher - 61.4% [9] and at our own clinic 67.4% (Table 5).

The further development in early neurological and neurosurgical rehabilitation in relation to intensive care content and procedures facilitates the tendency towards shorter acute medical stays and eases the burden on intensive neurosurgical or anaesthesiological units caring for patients with SAH.

Weaning

Published weaning rates from early neurological and neurosurgical rehabilitation (unselected diseases) in Germany are 68.3% [17], 69.8% [16], 78% [3] and 90.5%, respectively [25]. The weaning rate for patients with SAH is between 86.2% and 90.2% (Table 5). The median duration of weaning was 11.5 and 8.5 days, respectively (Table 5). These values demonstrate that in early neurological and neurosurgical rehabilitation there is now a high level of expertise in respiratory medicine and that patients requiring ventilation after SAH have very good chances of being successfully weaned despite often running the gamut of possible complications.

Decannulation Rates

Even with successful weaning, many patients in early neurological and neurosurgical rehabilitation remain dependent on a tracheostoma, as neurogenic dysphagia frequently develops which due to the associated risk of aspiration can mean that a blocked tracheal cannula is needed. The percentage of tracheotomised patients in the last few years in early neurological and neurosurgical rehabilitation has increased from 40% [28] in an unselected population of patients to up to 89% in patients with SAH (Table 6). Decannulation rates of 65.7% and 68.3%, respectively, (Table 5) indicate that under intensive swallowing

rehabilitation over two thirds of patients with SAH can be weaned from the tracheal cannula, even if severely affected.

Length of Stay in Early Neurological/Neurosurgical Rehabilitation

The average length of stay in early neurological/neurosurgical rehabilitation for patients after SAH in 2013 was 62.6 ± 116.1 days (median 38 days) in Hessen as a whole and $74.5 + 71.6$ days (median 37 days) at our own clinic. These values are highly consistent with those of other studies [3, 12, 18] in patients after SAH. Since 2002 there has been a gradual decrease in the lengths of stay for unselected patients, including patients post SAH, from 57 days in 2002 [12] to 37 and 38 days (Table 5) for SAH patients, in whom furthermore the course tends to be more fraught with complications. Alongside the increasing complexity and modalities of intensive therapy (e.g., ventilation), must also be considered. The reduction in the length of stay is most likely caused by the change in the billing system to flat rates per case and an increasingly restrictive attitude on the part of health insurers towards paying for the respective services.

Typical Early Rehabilitation Issues

Based on Schönle's Early Rehabilitation Barthel Index [23], Table 6 details the improvements in the respective items over the course of early rehabilitation therapy, which range from 43%-90% in Hessen as a whole and 56%-86% at our own clinic. It demonstrates that early neurological and neurosurgical rehabilitation, both in relation to medical stabilisation (e.g., termination of intensive care, weaning off ventilation, weaning off tracheostoma) and in relation to increased quality of life (e.g., improvement of swallowing disorders) and the establishment of conditions for further rehabilitation therapy or outpatient care (e.g., reducing orientation and behavioural disorders requiring supervision), constitutes a significant contribution in the care chain for patients after subarachnoid haemorrhage.

Transfer Rate in Subsequent Rehabilitation Phases

The reported transfer rates from early neurological and neurosurgical rehabilitation to subsequent rehabilitation phases are between 33.4% [28], 39.5% [18] and 55.4% [3] for unselected patient groups and 42.9% for patients post SAH [12]. However, agreements at the federal state level on phase transition should be considered here, meaning that the comparability of these figures is limited. At our own clinic, a comparable value of 43.5% is achieved (Table 7), whereas in Hessen as a whole it is somewhat lower (Table 7).

Table 7. Discharge from early neurological/neurosurgical rehabilitation

Population	Hesse, total (n = 175)		Bad König (n = 46)	
	n	%	n	%
Goal of transfer				
Home with non-professional assistance	6	3.4	2	4.4
Home with professional assistance	12	6.9	5	10.9
Inpatient rehabilitation (Phase C/D)	45	25.7	20	43.5
Alternative early rehabilitation	26	14.9	1	2.2
Transfer to acute hospital (subsequent readmission)	42 (28)	24.0	6 (4)	13.0
Care home	37	21.1	9	19.6
Deceased	7	4.0	3	8.7

Table 8. Functional outcome at the end of early neurological/neurosurgical rehabilitation based on the modified Rankin Scale

Population		Hessen, total (n = 175)		Bad König (n = 46)	
Score	Definition	n	%	n	%
0	No symptoms	3	1.7	0	0
1	Symptoms with no relevant functional deficit	2	1.1	0	0
2	Mild functional deficit	11	6.3	6	13.0
3	Moderate functional deficit	24	13.7	5	10.9
4	Moderately severe functional deficit	58	33.1	13	28.3
5	Severe functional deficit	72	41.1	19	41.3
6	Death	5	2.9	3	6.5

Transfer Rate in Care Facilities

The reported percentage of patients transferred to care facilities from early neurological and neurosurgical rehabilitation is between 16.2% [3] and 18.2% [18] in unselected patient groups and 21.9% in patients post SAH [12]. The rates in Hessen as a whole and at our own clinic are comparable at 21.1% and 19.6%, respectively (Table 7).

Return Transfer Rate in Acute Care Hospitals

The rate of return transfer from early neurological and neurosurgical rehabilitation is between 11.4% [28] and 27.6% [18] and ensues primarily as a result of internal or neurosurgical complications [30]. Evaluation of the data from 2013 reveals a retransfer rate in Hessen as a whole of 24% and 13% at our own clinic, where an appropriate team of staff and equipment for intensive care are in place (Table 7). This is readily comparable with earlier data for patients after SAH at 10.5% [12]. With an appropriate intensive care setting, retransfers are almost exclusively limited to elective neurosurgical secondary interventions [our own data]. This shows that it is possible, with an appropriately designed early neurological and neurosurgical rehabilitation concept, to guarantee “one-stop” treatment and minimise transfers which can be stressful to patients and to some extent put them at risk.

Functional Outcome at the End of Early Neurological and Neurosurgical Rehabilitation

The modified Ranking Scale (mRS) is a frequently used instrument for evaluating the outcome after stroke. To some degree it must be stressed from our own experience that external evaluation scales are highly problematic in the evaluation of outcome or even quality of life. Usually a score of 1-3 on the mRS scale is rated as a good outcome. A good 20% of patients after SAH therefore achieve a good outcome from early neurological and neurosurgical rehabilitation, both in Hessen as a whole and at our own clinic. This value, though apparently low, must be viewed from the angle of initial disease severity: only severely and very severely affected patients after SAH are admitted to early neurological and neurosurgical rehabilitation, bypassing more mildly affected patients who enter later phases of rehabilitation or at best remain asymptomatic.

CONTINUING REHABILITATION (PHASE C)

Phase C is the link between early neurological/neurosurgical (Phase B) and follow-up rehabilitation (Phase D). Those treated are patients who can already actively participate in the programme but must still receive curative medical treatment and require a lot of nursing attention [4, point 3.2., page 12].

The patients must meet the entry criteria for Phase C [4, point 3.2.1., page 12]:

- Alertness, able to comply with simple commands, sufficient ability to actively participate in the treatment measures of 30 minutes each
- Ability to communicate and interact
- Mobilised in a wheelchair for 2-4 hours at a time
- Vital signs and autonomic nervous system stable with no need for intensive medical supervision/treatment
- No further need for ventilation
- Comorbidities must not hinder mobilisation
- No danger to self/others and no severe disturbances to social behaviour in small groups

However, in contrast to rehabilitation during follow-up (Phase D), the patients to a large extent still depend on assistance in activities of daily living. The overriding aim of continuing rehabilitation is to improve independence in activities of daily living (ADL) and to restore the basic function of the nervous system through to the full capacity to act. Moreover, the further rehabilitation potential and long-term prospects should be clarified, a long-term treatment plan established, and continued care planned and introduced [4, point 3.2.2., page 13].

FOLLOW-UP REHABILITATION (PHASE D)

With growing independence in activities of daily living, but persistent motor deficits and mental disturbances that frequently interfere in working life and the daily routine, follow-up rehabilitation (Phase D) can begin upon achieving a Barthel Index score of approx. 65-70 points [29], indicating a general ability and willingness to cooperate as well as the capacity to act and learn. The main aim of Phase D is to achieve complete independence in everyday life and ideally facilitate the professional reintegration of those patients of working age.

PRESERVATIVE NON-HOSPITAL NURSING CARE (PHASE F)

If motor deficits in particular should limit activities of daily living, preservative non-hospital nursing care (Phase F) while continuing treatments on an outpatient basis is indicated. This nursing care can be carried out both at home and also in an institutional setting, such as in care homes or specialist nursing homes with treatments adapted to the patient's condition.

ACKNOWLEDGMENT

The authors wish to thank Dr. Med. B. Misselwitz, MPH, Head of the Institute of Quality Assurance Hessen at the Hessische Krankenhausgesellschaft e. V., Frankfurter Strasse 10 – 14, 65760 Eschborn for providing the data used in this article.

Chapter 78

COGNITIVE PLASTICITY AFTER SPONTANEOUS SUBARACHNOID HAEMORRHAGE

Christine Brand

Department of Neurosurgery, University of Ulm, Ulm, Germany

ABSTRACT

Patients who suffer spontaneous subarachnoid haemorrhage (SAH) often find themselves in the full swing of life, not only personally but also professionally. It is a radical event that has a dramatic effect on a patient's physical and psychological well-being. More than 50% of all SAH patients describe cognitive deficits that have a negative impact on quality of life. The exact causes of cognitive deficits are not yet known. However, patients develop everyday strategies with which to compensate for these deficits, such as writing themselves notes. One of the most reported impaired functions is working memory, irrespective of the time at which they were examined. Never the less, the ability of the brain to restore or compensate for functions that have been lost plays a very important role following spontaneous SAH. It is essential to the success of rehabilitation, as well as the social and professional reintegration of the patient to identify cognitive deficits and to train them.

Keywords: SAH, cognitive plasticity, quality of life, rehabilitation, cognitive deficits

Patients who suffer spontaneous subarachnoid haemorrhage (SAH) often find themselves in the full swing of life, not only personally but also professionally. It is a radical event that has a dramatic effect on a patient's physical and psychological well-being and thus has a negative impact on quality of life [1, 2]. Patients who outwardly appear to have achieved a good therapeutic outcome, implying that they have no obvious disorders such as palsy or speech defects, are often still burdened by less noticeable deficits. Such deficits are immediately apparent to patients themselves, of course, as well as to their family [3]. Patients very often describe deficits in terms of working memory, concentration and attention [4].

Conversations involving a number of people prove difficult to follow. Professionally they become less resilient, finding that their working lives are more of a strain than before the haemorrhage. Co-workers and superiors expect the same level of input from the patient, who is no longer written off sick and has no noticeable signs of illness. Cognitive deficits also lead to potential conflicts at home. Patients feel misunderstood and often become emotionally withdrawn.

After spending approx. two to four weeks under critical neurosurgical care, patients with spontaneous SAH are transferred for neurological follow-up treatment, which as a rule lasts three weeks. Following the inpatient stay, the patient is discharged to the care of his or her family doctor. In Germany, referral to a neuropsychologist is not current practice. Under normal circumstances, the patient undergoes gradual professional reintegration so as to resume work as before. In reality, this proves successful in only very few cases. Success is dependent firstly on the severity of the residual deficits, secondly on the demands of the patient's acquired skill.

The nature and intensity of cognitive deficits after spontaneous SAH have now been studied thoroughly [5-7]. Potential patient- and therapy-related influential factors have been described [7]. The progress over time, the potential for recovery, and with it plasticity, have been illustrated by diverse studies [5, 8, 9]. There is only speculation, however, as to the exact causes or pathogenesis. Awareness of the nature and scope, as well as the possible chances of improvement in the cognitive deficits, is essential for establishing a therapeutic basis for rehabilitation. Long-term morbidity can thus be minimised and at best prevented. The aim, however, should be to avoid cognitive deficits by administering optimised therapy. To achieve this, however, the causes must be known. Patient-related factors cannot be influenced by the treating physicians in the emergency department.

The aim of treating spontaneous SAH in the acute phase as well as later on during rehabilitation should therefore be to minimise the patient's cognitive deficits so as to prevent long-term morbidity.

SPECTRUM OF COGNITIVE DEFICITS FOLLOWING SPONTANEOUS SUBARACHNOID HAEMORRHAGE

More than 50% of all SAH patients describe cognitive deficits [1, 4, 7, 10, 11] that have a negative impact on quality of life. In the clinical routine, patients most often describe concentration-related deficits [4]. Difficulty concentrating is apparent not only during activities of daily living, but also at work. Diverse studies have examined the ability to concentrate following spontaneous SAH. Relevant concentration disorders were found in 11%-13% of the SAH patients studied [8, 12, 13]. Impaired memory, especially working memory, is the disorder that is most noticeable to the majority of patients after spontaneous SAH. Patients develop everyday strategies with which to compensate for these deficits, such as writing themselves notes. Various studies have reported working memory deficits in 28%-71% of all SAB patients, irrespective of the time at which they were examined [4, 7, 12, 14, 15]. Professionally, impaired concentration and memory deficits prove to be the biggest hurdle. Another area that can be affected is the speed of information processing, an issue that

has been found in 31%-65% of those affected [4, 7, 16]. In addition to the domains already mentioned, executive functions can also be impaired in SAH patients.

PLASTICITY AFTER SPONTANEOUS SUBARACHNOID HAEMORRHAGE

The ability of the brain to restore or compensate for functions that have been lost plays a very important role following spontaneous SAH. It is essential to the success of rehabilitation, as well as the social and professional reintegration of the patient. With today's ever-diminishing resources, the purpose and necessity for long inpatient stays, and thus costly inpatient rehabilitation programmes delivered by specially trained personnel, are called into question. Studies have been conducted to examine patients at varying times after spontaneous SAH in order to determine whether cognitive deficits have the potential to improve. It was demonstrated that skills in relation to speech comprehension, numeracy, verbal memory, attention, concentration and also executive functions do potentially improve [7, 8, 14]. The information processing rate appears to be a predictor for plasticity. The extent of the potential recovery depends on the severity of the bleeding and its localisation [17], as well as on patient-associated factors such as school education or age of the patient [7], and so cannot be influenced by the physician. Cognitive deficits can still improve even months after occurrence of the haemorrhage [7, 8, 16]. In practice this implies that one period of rehabilitation lasting several weeks is not sufficient. Specific, specialised outpatient follow-up care from a neuropsychologist is appropriate and necessary if an optimum outcome is to be achieved. This appears to be the only way to guarantee the best possible professional reintegration of the patient. Social integration could likewise be positively influenced in this manner. Long-term morbidity could thus be sustainably reduced.

FACTORS INFLUENCING COGNITIVE DEFICITS

To optimise therapy in the emergency department and create the best conditions for subsequent rehabilitation, the factors that influence cognitive performance and the quality of life of patients with spontaneous SAH have been examined [18-20]. In doing so, it is useful to divide these factors into two categories: patient-related and treatment-related factors. In the emergency setting, physicians cannot influence patient-related factors. School education, profession, laterality, pre-existing cardiac diseases, obesity, hyperlipidaemia, diabetes mellitus and nicotine abuse all appear to have a significant influence on the therapeutic outcome. Treatment-related factors are the primary focus of the attending physician. Some studies have looked at whether coiling or clipping of a ruptured aneurysm offers a better treatment outcome. The type of treatment does not appear to influence the cognitive treatment outcome, however [8]. Various conventional classification systems have been considered as potential prognostic tools. None could ultimately live up to expectations. Neither the Fisher score, which describes the extent of the bleeding based on diagnostic imaging, nor the Hunt and Hess scale, which documents the initial clinical condition, permitted a satisfactory estimation to be made of the treatment outcome [21]. Another popular system for grading the clinical condition is the Glasgow Outcome Score, though it does not describe the presence of

cognitive deficits. The localisation of the aneurysm also appears, moreover, to have no impact on the existence of cognitive deficits [8, 22, 23].

POSSIBLE CAUSES OF COGNITIVE DEFICITS, THERAPEUTIC STRATEGIES AND PROSPECTS

The exact causes of cognitive deficits are not yet known. Theories abound, however. It stands to reason that the bleeding itself is the cause of all evil [22]. On the one hand the haemorrhage causes localised damage, as well as deficits theoretically due to the effects of the bleeding. These include impaired CSF circulation, vasospasms and ischaemia. Or is the acute rise in intracranial pressure following rupture of the aneurysm responsible for the cognitive deficits [7]? It appears at least to explain why focal lesions also influence cognitive areas suspected to exist in other regions of the brain. From another angle, numerous functions such as memory may not be focussed on just one area of the brain. This subject certainly needs to be examined more closely.

In conclusion, it should be stated at least that cognitive deficits often develop in patients with spontaneous SAH and negatively influence quality of life in the long term. As a result, long-term morbidity increases. Cognitive deficits can be treated specifically by means of rehabilitation therapy. There is still a chance after several months that these deficits will improve. Outpatient follow-up care from a neuropsychologist subsequent to initial inpatient rehabilitation is therefore beneficial to the patient.

Chapter 79

HEALTH-RELATED QUALITY OF LIFE FOLLOWING SPONTANEOUS SUBARACHNOID HAEMORRHAGE AS AN ASSESSMENT CRITERION FOR THERAPEUTIC OUTCOME

Thomas Kapapa

Department of Neurosurgery, University of Ulm, Ulm, Germany

ABSTRACT

Health-related quality of life serves as a supplement to the clinical criteria for determining the outcome of therapy. The lack of a higher-level definition for the term quality of life, however, is still problematic, but there is a general consensus on the individual approach and understanding as to what the term entails. The aim of this chapter is to make it clear that a good or very good clinical treatment outcome is not to be regarded as equivalent to good or very good quality of life. The subjective perception and attitude of the patient towards his or her personal situation after the haemorrhage are equally important when it comes to evaluating the treatment outcome. The individual assessment of the treatment outcome also very much depends on the expectations and experience of the patient. This should be taken into account when determining the said outcome.

Keywords: outcome; rehabilitation; cognition, reintegration

Aristotle: “We are what we repeatedly do. Excellence, then, is not an act, but a habit!” But what happens when external or internal factors prevent us from continuing to do what we normally do so well? When is something new to be regarded as a habit? This rather philosophical approach in dealing with quality of life often cannot be reconciled with the concept of health-related quality of life. This is due on the one hand to the context within which quality of life needs to be understood. Terms such as lust for life, vitality, courage and trials of life are used synonymously. There are core intellectual elements such as political

philosophy, social philosophy, environmental philosophy and medical ethics that deal with the term quality of life. Time, in the context of the here and now as well as transition, is another important factor for determining quality of life. All the differences described here lead us to surmise that there is no all-encompassing definition for quality of life.

The author sees the approach to quality of life in the medical context as a means of optimising patient care. To the author, health-related quality of life represents a collection of criteria reflected by objectives, values and principles, such as the certainty and length of life and a defined level of health, the freedom to seize opportunities, or personal and social recognition. Yet to the author health-related quality of life also inevitably includes criteria with alternative approaches to quality of life, such as the existence of economic conditions for achieving an ideal situation as expected by a society or self-imposed goals [1-3]. With this theory in mind, clinical endpoints are to be understood in the context of subjective satisfaction, psychosocial interaction and forward-looking behaviour [4].

The advances in the treatment of this complex condition, already described in this book, are so effective that mortality now accounts for only roughly a third of patients after one month. Results from the 1960s came to far more inferior conclusions, namely that approx. 33% of patients died before reaching a hospital and 27% of patients died during treatment [5, 6]. The Glasgow Outcome Scale and Modified Rankin Scale are the methods most commonly used for assessing the treatment outcome [7-9]. Not only is the rate of those surviving spontaneous subarachnoid haemorrhage increasing, but also the number of patients with a good treatment outcome [10]. The outcome of treating spontaneous subarachnoid haemorrhage is often described as “good”, “moderate”, or “poor”. There has been a clear improvement in the survival rate to almost 50% of patients classified in line with general criteria as having a “good” or “very good” outcome from such an event [11-14]. These categories are consistent mostly with functional neurological deficits. Little consideration is given in these ratings to psychological, cognitive and social components. The quality of life of many patients, despite their physical well-being, may still be impaired [3, 15]. It is not unusual to find that such disorders are caused by neuropsychological and cognitive deficits [15-17]. It is generally agreed that spontaneous subarachnoid haemorrhage has a considerable impact on quality of life [14].

The treatment outcome has a more lasting and profound impact than the patient's condition at discharge alone. It must be judged in the context of the patient's normal family life, routine social ties and social participation, as well as usual physical and mental achievements. Clinical parameters do not suffice to describe this situation. It has long been known that a disease can alter the conditions and thus the quality of life over an extended period of time [18]. Accordingly, health-related quality of life can be judged as 1) quality of personal situation, 2) satisfaction with personal situation, or 3) a combination of both [18]. Hence, the clinical treatment outcome is always an integrated part of the individual personal situation. To gain an insight into such a situation, health-related quality of life is useful. It is an illustration of the disease, the clinical outcome of treatment and the personal situation. It places the “patient” above the “disease” as the objective, and also establishes a connection between the two. This provides the opportunity to compare rational health indications, objective clinical ratings and progress against the patient's subjective views and treatment outcomes.

The prevailing method for measuring quality of life is the questionnaire or interview. Various quality-of-life questionnaires are available for collating information universally on

general characteristics, or specifically on disease-related characteristics [3, 14]. At present, there is no quality-of-life tool for the neurological/neurosurgical field that combines the objective and subjective indicators for satisfaction related to spontaneous subarachnoid haemorrhage.

Physical performance and role identity, i.e., the behavioural expectations (and behavioural codes) placed by others on the respective role holders, such as mother, father, employee, comforter, etc., are most affected by spontaneous subarachnoid haemorrhage and are reported in up to 60% of patients with diminished quality of life [19, 20]. Anxiety and depression are described by more than half of the patients with impaired quality of life [19, 20]. Both have a considerable influence on psychosocial interaction in the community. This is reflected in diminished vitality (43%) and emotions (40%) [19], and affects the ability to work. The ability of a patient to function socially after suffering spontaneous subarachnoid haemorrhage is influenced if physical identity as well as mental and emotional health are impaired [21]. A restriction to the quality of life after spontaneous subarachnoid haemorrhage may go unnoticed and untreated for a long time [2]. This situation is also unaffected by an improvement in residual physical deficits [22].

Descriptions of how the quality of life is influenced by clinical factors are inconsistent [14, 23]. The parameters most commonly reported, however, are age, sex, residual physical factors, neurological status on admission and Glasgow Outcome Score [14, 19, 22-29]. In this regard better scores are attained with the clinical factors, along with better results in terms of health-related quality of life. The Hunt & Hess Score and Fisher Score are seldom described as influential [27, 30].

In summary, it is evident that spontaneous subarachnoid haemorrhage has a lasting, negative impact on health-related quality of life. Such an influence is multifactorial, affecting several aspects of quality of life yet primarily the physical and emotional domains. Similarly, certain roles are affected which prove difficult to rehabilitate following critical care. It makes sense to document health-related quality of life three to six months after reintegrating the patient into his or her daily life. It is at this point that the implications of the haemorrhage can be evaluated and the therapeutic outcome can be further improved. Treatment of impaired health-related quality of life signals an improvement in the overall treatment outcome. Treatment is interdisciplinary, involving physical and occupational therapists, neuropsychologists and psychologists, and if necessary specialists in psychosomatic medicine and psychiatry, as well as social workers. It also engages the patient's entire family and circle of friends. If the improvement in the purely physical and clinical criteria of the treatment outcome following spontaneous subarachnoid haemorrhage comes to a standstill due to the fact e.g., that no new clips or coils, no new minimally invasive approach, and no new treatment for delayed cerebral ischaemia or hydrocephalus is forthcoming, another way in which to further enhance the treatment outcome is to define, document and instigate therapy with a view to health-related quality of life.

Chapter 80

EXPERIMENTAL MODELS FOR THE STUDY OF SUBARACHNOID HAEMORRHAGE

Nicole A. Terpolilli

Department of Neurosurgery, Ludwig-Maximilians University of Munich,
Munich, Germany

ABSTRACT

Various animal models have been developed in order to study the pathophysiology of SAH and to evaluate possible pharmacological treatment strategies. The following chapter discusses the most widely used techniques and animal models.

Keywords: experimental SAH, animal models of SAH, MCA perforation model

Various experimental animal models of subarachnoid haemorrhage have been developed to investigate pathophysiological mechanisms and to trial possible new treatment strategies. The following chapter will explore the most frequently employed techniques. Haemorrhage is most commonly induced either by a single or multiple injection of blood into the subarachnoid space or by puncturing/perforating a vessel in the circle of Willis (CW). In the last 30 years experiments were frequently carried out on primates as their physiology and anatomy is similar to that of humans. This enabled the use of clinical examination methods such as digital subtraction angiography and CT angiography for measuring cerebral blood flow and detecting vasospasm. More recently, rodents are favoured as laboratory animals given the scarce availability of primates; besides animal welfare issues and ethical and financial motives, the mouse model in particular is gaining in importance because it offers the possibility of genetic modification, i. e. the creation of transgenic mice. Furthermore, improved *in vivo* imaging techniques, such as two-photon microscopy or magnetic resonance imaging, provide increasingly accurate insights into the processes of posthemorrhagic microcirculation, even when using small laboratory animals.

INJECTION MODELS

Bagley described an animal model for investigating subarachnoid haemorrhage as early as 1928: autologous venous blood was mixed with cerebrospinal fluid and injected into the cisterna magna of dogs [1], which triggered the typical cardiovascular/systemic consequences of human pathology; in some cases multiple injections were required to achieve this effect. Subsequently, the model was adapted for different species, injection sites and injection techniques. Heparinised or non-heparinised whole blood (autologous or heterologous) or haemolysate is injected. The cisterna magna injection model is used extensively in dogs [2-4], different monkey species [5-8], rats [9-12], and mice [13, 14]. Since in the majority of patients aneurysms, and therefore also the bulk of the haemorrhage, are located in the anterior portion of the circle of Willis, it has been suggested that animal models with injection into the anterior cisterns may be better suited to reproduce the clinical phenotype. While transfrontal or transorbital blood injection into the prechiasmatic cistern in monkeys [15, 16] or dogs [17] produced inconsistent results with regard to the development of vasospasm and neurological damage, the model of prechiasmatic blood injection in rats [18, 19] reliably produces subarachnoid haemorrhage with corresponding deficits in a minimally-invasive fashion and with negligible operative morbidity; in this frequently used model auto- or heterologous blood is injected stereotactically into the prechiasmatic cistern via a small frontal burrhole.

In summary, injection models are easy to standardise, particularly with regard to haemorrhage volume, technically easy to implement (compared to other techniques) and reliably result in a range of quantifiable secondary SAH complications, such as decreased cerebral blood flow, intracranial hypertension, neuronal damage, and secondary changes at the cellular and microcirculation levels.

However, injection techniques also have distinct disadvantages as not all aspects of the pathophysiology of SAH can be modelled. In particular, the kinetics of stereotactic volume injection, which usually is performed over minutes, do not correspond to those of a ruptured arterial vessel where haemorrhage happens within seconds with high pressure. Accordingly, intracranial pressure in injection models does not follow the same course as ICP in the human pathology, furthermore the decrease of cerebral blood flow after injection is only short-lived [20]. As the initial and sharp ICP peak and/or the consecutive global cerebral ischaemia are decisive factors for early pathophysiological changes (early brain injury, EBI), it is as yet unclear to what extent injection models are suited to investigating acute pathophysiological changes after subarachnoid haemorrhage.

To better adapt the dynamics of injection-induced subarachnoid haemorrhage to the real-life situation, arterio-intrathecal shunt models were developed. Steiner et al. developed a canine model with femoro-intrathecal shunt in 1975 [21, 22] in order to investigate the pathophysiology of acute mortality after subarachnoid haemorrhage. This approach was modified in the rabbit model by Marbacher et al. to create the so-called shunt model [23]: The cisterna magna of rabbits is transcutaneously cannulated and connected to a catheter that has already been placed in the subclavian artery. When this bypass - which is initially closed with a clip - is opened subsequently, blood enters the subarachnoid space proportional to and dependent on the arterial blood pressure. Afterwards, the shunt is sealed. Previous results with this model indicate that the acute phase of subarachnoid haemorrhage, which is characterised

by a CPP-independent decrease in cerebral blood flow [24, 25], may be better reproduced than in other injection models [26].

Re-bleedings which frequently occur and may complicate the clinical course are another factor that cannot be modelled using single injection techniques.

As the occurrence of (angiographically detectable) delayed vasospasm is associated with the extent of subarachnoid blood volume, the injection model may be carried out in a staged fashion, injecting twice or multiple times [27-31] thereby significantly increasing the severity of SAH and of all posthaemorrhagic complications. However, even after double blood injection, the acute decrease of cerebral blood flow is much less pronounced than the CBF drop observed in patients and in the perforation models described below [20, 32]. Lastly, vascular injury and/or endothelial damage, important pathophysiological features of aneurysmal subarachnoid haemorrhage, are missing in the injection model.

CIRCLE OF WILLIS: PERFORATION MODELS

In order to adequately model vascular injury and the arterial haemorrhage kinetics of subarachnoid haemorrhage in an experimental setup, large animal models were developed from the 1960s onwards; SAH was triggered by direct vascular puncture of the internal carotid artery [ICA, 33-35], middle cerebral artery [MCA, 36], or arteries of the posterior circulation [37-39]. Catheter-assisted [40] or endoscopic [41] procedures without craniotomy have also been described. In 1995, Bederson was the first researcher to describe the filament perforation model in rats [42]; in this non-invasive technique, a monofilament is introduced via the external carotid artery into the internal carotid artery and then advanced intracranially. The circle of Willis is perforated at the MCA bifurcation, the filament is then quickly removed. Over the years, several modifications of the MCA perforation model have been introduced: in order to control the intensity of haemorrhage, the common carotid artery was ligated [43]. However, this reduces global cerebral perfusion and leads to an increase in posthaemorrhagic global cerebral ischaemia. Use of different filament sizes (3-0, 4-0, 5-0) may be more suited to influence haemorrhage volume and, thus, severity [44]; moreover, replacing the polymer filament with Wolfram wire may help to reduce the perioperative complication rate [45]. Important pathophysiological features of SAH are reliably reproduced in the MCA perforation model: a sharp increase in ICP with simultaneous decrease in cerebral perfusion, the Cushing reflex, and numerous secondary complications such as brain oedema formation, (histologically detectable) neuronal damage and neurological deficits; re-bleeding intermittently occurs and can be quantified [46]. In the late 1990s, the endovascular filament perforation technique was first described in mice and thus could also be used in transgenic mouse models [47-49], but the reported mortality and secondary posthaemorrhagic damage showed wide variations. The routine use of laser Doppler flowmetry and intracranial pressure measurement during perforation helps to prove correct SAH induction and thereby enables a high level of standardisation of the method [50, 51]. Combining the perforation mouse model with transgenic alterations and improved *in vivo* imaging techniques such as intravital microscopy led to important insights into the pathophysiology of the early phase after subarachnoid haemorrhage. This early brain injury is characterised by a significant disturbances of the cerebral microcirculation, involving among other things microthrombosis

of cerebral vessels [52, 53], microvascular constrictions (so called microvasospasms) [54], and impaired cerebrovascular CO₂ reactivity [55].

The drawbacks of the perforation model are the challenging and complex surgical technique and the inability to fully control the blood volume. However, after an appropriate training phase, perioperative morbidity decreases significantly. By continuously monitoring intracranial pressure and cerebral blood flow during induction of SAH and at different time-points thereafter, standardisation of bleeding intensity can not only be guaranteed, but also documented. A further albeit minor point of criticism in the perforation model is the lack of a “non-haemorrhage” control group: sham operated animals, in which the filament is introduced but the circle of Willis is not punctured, usually are used as controls. Unlike in injection models, where sham-operated animals are injected saline to separate the effect of intracranial volume augmentation from the effect of blood components, these animals do not undergo any physiological changes. However, in summary, the perforation model of subarachnoid haemorrhage is a well-established tool for simulating most facets of SAH pathophysiology and - despite a few limitations and higher (technical and surgical) complexity than other techniques - the only SAH model that simulates mechanical trauma from vascular rupture. Most studies that address the mechanisms of early brain injury [56, 57] use this model.

OTHER SAH MODELS

Placement of blood clots onto or around the circle of Willis vessels leads to delayed vasospasm that is clearly detectable on angiography or by Doppler sonography; this technique has been frequently used for chronic SAH studies and drug trials [58-61]. However, a craniotomy and invasive operative procedure are needed to position the blood clot, limiting the successful use of this method to larger species such as dogs and monkeys. The costly equipment and surgical expertise needed for large animal experiments, the increasing restrictions placed on primate experiments, and the shift in research focus to early disturbances in the cerebral microcirculation, have severely limited the dissemination of the clot model. Currently, the primate model is used in a few centres to investigate delayed vasospasms [62, 63].

Various studies report the successful and standardisable induction of intracranial aneurysms [64-66]; however, it has not yet been possible to reliably trigger subarachnoid haemorrhage in these models. Further development of this method or its combination with existing perforation techniques may make a model of aneurysmal subarachnoid haemorrhage feasible in the future.

CONCLUSION

There are a multitude of experimental techniques for inducing subarachnoid haemorrhage. All models have distinct advantages and disadvantages; given the complex human pathology no single model will adequately represent every nuance of the disease. Perforation models are technically complex and more surgically/manually challenging than

other techniques, but perforation-induced SAH appears to be most closely related to the kinetics of haemorrhage, vascular trauma in ruptures, elevated ICP, decreased CBF and other secondary posthaemorrhagic processes of human pathophysiology. In transgenic mouse models this method, combined with novel imaging and visualisation techniques, enables examination of all aspects of SAH pathophysiology, particularly in the early phase (<72 hours) after haemorrhage; if necessary, results obtained in the rodent model then can be tested/verified in clinically relevant, large animal models with respect to their suitability for use in SAH therapy.

University of Leicester, United Kingdom

ABSTRACT

Vascular imaging has seen a revolution over the last two decades, since the introduction of endovascular surgery, which has gradually become routine practice, and the development of advanced cross-sectional imaging modalities with higher fidelity and accuracy. Duplex ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and conventional digital subtraction angiography (DSA) are currently the main imaging modalities in the armamentarium of vascular surgery. Given the recent advances in software and imaging devices, DSA is now typically reserved for intervention rather than diagnosis. The modern vascular surgeon needs to be aware of the limitations and advantages of each imaging modality, and should be able to diagnose and plan therapeutic procedures, involving either open or endovascular reconstruction, independently. This chapter covers the basics behind the main imaging methods in contemporary vascular practice with an aim to aid diagnosis and management of the relevant pathologies.

INTRODUCTION

Vascular imaging has seen a revolution over the last two decades, since the introduction of endovascular surgery, which has gradually become routine practice, and the development of advanced cross-sectional imaging modalities with higher fidelity and accuracy [1]. Duplex ultrasound (US), computed tomography (CT), magnetic resonance imaging (MRI), and conventional digital subtraction angiography (DSA) are currently the main imaging modalities in the armamentarium of vascular surgery. Given the recent advances in software

and imaging devices, DSA is now typically reserved for intervention rather than diagnosis. The modern vascular surgeon needs to be aware of the limitations and advantages of each imaging modality, and should be able to diagnose and plan therapeutic procedures, involving either open or endovascular reconstruction, independently [2]. This chapter covers the basics behind the main imaging methods in contemporary vascular practice with an aim to aid diagnosis and management of the relevant pathologies.

CONTRAST IN VASCULAR IMAGING

The majority of the imaging modalities in vascular surgery require the administration of intra-arterial or intra-venous contrast agents to adequately picture the vasculature. Even ultrasound is now aided by the administration of contrast, to depict more complex anatomies, such as after endovascular interventions [3]. There are certain limitations and challenges associated with contrast administration that need to be discussed.

Several types of contrast media are available, based on the imaging modalities where they are used. Contrast media also differ in terms of molecular function and properties. Iodinated media are typically used in vascular imaging, and they may be either ionic or non-ionic. Non-ionic contrast is currently the most widely used medium, given the reduced risk for adverse reactions. Additionally, the vast majority of media used today are low or iso-osmolar, again due to reduced risk for anaphylaxis and nephropathy [4]. Any form of angiography, either CT or MR generated or conventional DSA, requires the administration of a contrast agent. That may lead to contrast induced nephropathy (CIN), which is an acute deterioration in renal function due to direct damage to the kidney, which happens at the level of the renal tubule [5]. CIN has conventionally been defined as an acute rise in serum creatinine levels of at least 25% compared to baseline and is associated with short and long term adverse outcomes [6-8]. Other definitions of acute kidney injury (AKI) have also been made available over the last decade, but are more applicable to interventions, such as endovascular aneurysm repair (EVAR), rather than diagnostic imaging modalities [5, 9]. Patients at increased risk for CIN or AKI after contrast administration include those with diabetes, hypertension, current smoking habit, critical limb ischaemia (especially in the case of existent tissue loss) and those with a baseline estimated glomerular filtration rate of less than 45ml/min/1.73m [5, 10]. The prevention of CIN and AKI in these patient groups is challenging and there are several proposed interventions with variable results, including the use of iso-osmolar contrast agents, adequate patient hydration using normal saline with or without sodium bicarbonate, premedication with N-acetylcysteine, ischaemic preconditioning, or angiography based on carbon dioxide contrast agents [5, 9]. Reno-protection should be guided by pre-existing risk-factors and most definitely contrast use should be avoided if possible. Gadolinium, a non-iodinate medium which is the contrast of choice in MR imaging, is less nephrotoxic but can also lead to a deterioration in renal function as well as interstitial nephritis and a rare type of nephropathy, gadolinium-induced nephrogenic systemic fibrosis, in high-risk patients – especially these with chronic kidney disease stage 3 and above at baseline [11-13]. MR-based angiography also requires fairly small doses of gadolinium (0.1mmol/kg), which may also explain the less pronounced impact on renal function. Carbon dioxide (CO₂) is an alternative contrast agent useful in both diagnostic and therapeutic procedures. Catheter-directed

injection of CO₂ results in a negative contrast image within the target vessel [14]; CO₂ is rapidly absorbed and is not nephrotoxic. However, it is very challenging to image below the knee lesions adequately [15] and most centres are not yet familiar with its use [14, 16]. Interestingly, several case-series of EVAR using CO₂ as a contrast medium have recently been made available [17, 18].

Several ultrasound contrast media are currently available, most in the form of “micro-bubbles” and various are under developments, hopefully with less nephrotoxic properties. These agents typically consist of micro-bubbles encased in a biodegradable-shell. These are injected whilst an ultrasound probe is used to visualize the vessel in question. The subsequent risk of nephropathy is less. There are no large studies available with regards to usage of contrast-based Duplex ultrasonography in the diagnostic assessment of the peripheral vasculature; however, this modality has shown promising results in post-EVAR follow-up for endoleak [19, 20].

DIGITAL SUBTRACTION ANGIOGRAPHY

Conventional angiography involved the selective catheterisation of a target vessel or territory with an angiographic catheter, typically through a femoral (percutaneous) approach. Radiographic images are taken after contrast injection. Digital subtraction angiography (DSA) is almost always employed, which allows the subtraction of background tissue to provide a better picture of the vasculature, using simple software. DSA has been the gold standard for imaging the arterial and venous tree, but is currently being replaced in routine practice by more contemporary cross-sectional modalities that are less invasive and labour intensive. Given its invasive nature, DSA can be associated with access-related complications, such as haematoma, pseudoaneurysm formation, or inadvertent cannulation of an adjacent vessel [21]. To limit these, most interventionists will perform vessel-punctures under ultrasound guidance in contemporary practice. Other complications secondary to DSA include damage to the target vasculature, including dissection, thrombosis, vasospasm, and peripheral embolization or even rupture of the target vessel. Finally, there is an increased risk of CIN given that iodinated contrast is injected intra-arterially [5]. Given these risks, DSA is usually reserved for intervention or imaging of challenging anatomy, such as below the knee lesions or heavily calcified lesions where CT angiography and MR angiography may not be as sensitive. Additionally, DSA yields physiologic information, such as the measurement of pressure gradients across lesions and the ability to observe the flow of contrast through a vessel in real-time. This may particularly helpful in below the knee lesions and in patients where a low cardiac output does not allow adequate imaging with non-invasive modalities.

COMPUTED TOMOGRAPHY (CT)

Angiography based on images obtained by computed tomography (CT) has seen significant advances over the last three decades. The current modality of choice when using CT to image the vasculature is multi-detector CT angiography (MDCTA). Using intravenous contrast medium, multiple detectors travel in a helical orientation around the patient and

collect volumetric data (together with cross-sectional images), which are then displayed using relevant software. Typically, the volume of contrast required is 50 to 150 ml, depending on the patient's respiratory status, left ventricular function, localization of the disease, and the degree of anatomical detail that is necessary. Retrospective or prospective ECG synchronisation can be applied as well, which may be applicable especially when imaging the proximal aorta and dissections. The main differences between conventional spiral CT and MDCTA include the rapid acquisition speed for MDCTA and the fact that volumetric data are obtained, which allow in-depth analyses of the anatomy of the vessels. Reconstruction of the cross-sectional slices together with the volumetric data obtained via MDCTA is performed with relevant software using the following protocols: maximum intensity projection (MIP), vessel density ratio (VDR), and multi-planar reconstruction (MPR) [22]. Maximum intensity projection can provide pictures very similar to DSA but may exaggerate the degree of stenosis in the case of significant calcification; MPR cannot follow the tortuous course of certain arteries but it can very accurately depict intraluminal thrombus. Several solutions are being investigated to overcome these technical problems including curved MPR and digital subtraction imaging. Additionally, the latest generation devices provide even more detailed scanning and the subsequent quality of the images obtained is very similar to DSA. Another important advantage of MDCTA over DSA is the fact that the cross-sectional slices provide important information about the surrounding anatomy, which could not have been obtained using conventional angiography. Overall, MDCTA is a rapid and safe mode of imaging the vasculature. It has become the preferred method of imaging patients before EVAR (instead of DSA) [23] in order to plan the procedure and has largely replaced DSA as a diagnostic modality for peripheral arterial disease [24].

It has long been shown that EVAR can be safely planned using measurements obtained from reconstructed MDCTA images without the need for DSA. A typical EVAR protocol MDCTA scan includes acquisition of unenhanced, arterial contrast, and delayed post-contrast images. Unenhanced images provide a baseline examination against which apparent abnormalities in the arterial phase can be judged. Delayed images allow for the evaluation of slow endoleaks, especially type 2 endoleaks. MDCTA is in fact very accurate at depicting endoleaks, migration and other device-associated or anatomical complications following EVAR [25, 26]. Further classification with DSA may be necessary in the case of an endoleak, as up to 10% of endoleaks may not be classifiable based on CT reconstruction alone. However, most centres now employ MDCTA as the “gold-standard” in imaging endoleaks, at least at the first instance. Regarding routine post-EVAR follow-up, ultrasound has replaced MDCTA as the preferred modality for device surveillance given the as it is less expensive and does not involve contrast or radiation exposure. A recent meta-analysis has shown that unenhanced ultrasound has rather poor sensitivity for endoleak detection; however CEUS is highly sensitive [25].

MDCTA is also useful in the assessment and planning of peripheral arterial disease (PAD). In the evaluation of severe peripheral lesions, MDCTA has a sensitivity of 92% and a specificity of 97% when compared with DSA [27, 28]. When used after ultrasound imaging before intervention, it may lead to a change in the initial treatment strategy in up to 25% of cases. However, in contemporary practice, given the increasing accuracy of ultrasonography, planning of intervention based on ultrasound alone is acceptable in the majority of cases. MDCTA is associated with lower radiation dose than DSA, and consistency in treatment recommendations based on MDCTA is excellent [28]. Regarding carotid artery disease,

MDCTA is a useful adjunct to ultrasonography. It bears a negative predictive value of almost 100% for stenoses between 50% and 70% [29]. All the carotid trials have used ultrasonography as the “gold-standard” for imaging; MDCTA should be reserved for recurrent disease (re-stenosis), and plaques that have significant distal extension, as part of pre-operative assessment and planning.

Finally, coronary CTA has recently emerged as a promising non-invasive method for the detection and coronary artery disease (CAD). A recent randomized trial confirmed multidetector MDCTA as a modality that has equal clinical applicability as conventional DSA in diagnosing and planning treatment for CAD [30].

MAGNETIC RESONANCE IMAGING (MRI)

Angiography can be performed with or without contrast (intravenous) agents using MRI technology. MR-angiography (MRA) without contrast can be performed by imaging the intrinsic motion of protons in flowing blood using time-of-flight (TOF) sequences. However, the resolution is not optimal and the procedure is timely. Gadolinium can be administered intravenously to obtain better resolution pictures. Similar to MDCTA sequences, post-capture reconstruction can take place using maximum intensity projection (MIP), vessel density ratio (VDR), and multi-planar reconstruction (MPR). Gadolinium-enhanced MRA is mainly used to image peripheral arterial disease (PAD), renal artery disease (RAD) and carotid artery disease (CAD) in contemporary practice.

MRA and Peripheral Arterial Disease (PAD)

MRA is becoming an increasingly common modality in PAD to image, mainly, infrainguinal and infrapopliteal disease; MRA reconstructed images using MIP predicted have a sensitivity of 97%–100% and a specificity of 95%–99% compared to DSA in PAD. However, MRA may significantly over-estimate stenoses in the peripheral vasculature, more so than MDCTA, and is associated with increased cost. Interestingly, MRA for preoperative planning has been associated with a higher surgical re-intervention rate when compared with MDCTA.

MRA and Carotid Artery Stenosis (CAS)

Carotid disease is frequently assessed with MRA reconstructed images, mostly in lesions where a stenosis has already been shown using Duplex ultrasonography. Generally, in CAS MDCTA may underestimate clinically relevant grades of stenosis and is mostly helpful in assessing carotid occlusion as suggested by ultrasonography, whilst MRA is more comparable to conventional DSA, even though it may still give rise to a 5.0% overestimation of stenosis [31]. Overall, MRA is a useful, non-invasive modality for assessment of CAS with a more than 70% stenosis [31], even though it cannot be recommended as first line imaging modality in assessing patients with cerebral events, mostly due to cost (compared to

ultrasonography). Interestingly, a meta-analysis suggested that MRA has a better discriminatory power compared with ultrasonography in diagnosing 70% to 99% stenosis and is as sensitive and specific as DSA in the evaluation of CAS [32].

MRA and Renal Artery Disease (RAD)

MRA has been used extensively in evaluating patients with RAD. Previously, most patients had to undergo gadolinium enhanced MR imaging, which had a good diagnostic accuracy, but was limited due to cost and use of contrast, especially given that this population is more likely to present with renal dysfunction. More recent MR imaging protocols, such as non-contrast balanced steady-state free precession MRA have been assessed in patients with RAD, and a meta-analysis of 10 high-quality studies comparing this technique with gadolinium enhanced MRA or MDCTA has shown a pooled sensitivity of 0.88 (95% CI, 0.83-0.91) and a pooled specificity of 0.94 (95% CI, 0.93-0.95) [33]. Another type of MR imaging, time-spatial labeling inversion pulse (time-SLIP) MRA has also recently been assessed in imaging of RAD without contrast, showing a specificity of 93% and accuracy of 90% compared to contrast-enhanced MDCTA [34]. Overall, MRA is becoming increasingly the study of choice in imaging the renal arteries, with or without gadolinium, depending on local availability and expertise.

DUPLEX ULTRASONOGRAPHY

Pulse-wave Doppler ultrasound and grey-scale ultrasound imaging are obtained and combined to provide cross-sectional imaging of the vasculature with real-time information regarding blood-flow in duplex ultrasonography (DU). Colour Doppler may be used as well to further augment assessment of blood flow. This non-invasive and dynamic method of imaging the vasculature has found several applications in vascular medicine and vascular surgery. DU is currently the imaging modality of choice in the initial assessment of patients with peripheral arterial disease (PAD), venous disease (VD), surveillance of both grafts and endovascular devices after endovascular aneurysm repair, as well as carotid artery stenosis (CAS). DU is also used more frequently in the assessment of abdominal vasculature as the experience of the operators and imaging capacity of the devices are expanding. Finally, DU is the imaging study of choice in screening the general population for abdominal aortic aneurysm. Clinical studies have shown that the quality of DU depends on the user's level of experience and that some arterial segments may be visualised more readily than others. However, it does not involve radiation or the use of contrast media and is relatively cheap, especially compared to modalities such as MDCTA and MRA. The main patient-associated limitations of DU include: heavily calcified vessels, very low flow (such as in the case of a low cardiac output), significant tissue oedema, obesity and presence of ulceration.

DU in Peripheral Arterial Disease

Ultrasound is now routinely used in the assessment of the vast majority of patients with peripheral arterial disease (PAD). It has been shown to be accurate in assessing stenoses of the vasculature in the upper and lower limbs [35, 36]. More specifically, several studies have looked at DU in isolation in planning peripheral bypass reconstruction in an emergency or semi-elective setting [37-40]. One year patency rates after bypass to the popliteal segment using DU as the sole pre-operative imaging modality are similar to those when using DSA or MDCTA reconstruction [37, 40]. Even infra-popliteal disease can be accurately assessed to allow planning for distal bypasses using DU, with similar patency rates compared to procedures planned with DSA [39, 41].

Besides baseline assessment and planning, DU is an acceptable imaging modality for surveillance of bypass conduits. Interestingly, a recent randomized controlled trial with 594 participants undergoing peripheral bypass demonstrated that intensive surveillance with DU did not show any additional benefit in terms of limb salvage rates for patients undergoing vein bypass graft operations, but it did incur additional costs [42]. If an imaging-guided surveillance programme is in place, DU is usually the modality of choice, especially given that it performs very similarly to MDCTA or MRA [43, 44]. Testing frequency should be individualized to the patient, type of bypass, and degree of stenosis if one is indeed depicted. Graft surveillance should focus on the identification and repair of critical stenosis (peak systolic velocity exceeding 300 cm/s, and peak systolic velocity ratio across the stenosis exceeding 3.5) correlating with more than 70% diameter-reducing stenosis [43]. A graft surveillance programme should result in a graft failure rate of less than 3% per year [43].

DU in Carotid Artery Disease

A large analysis of patients with carotid artery stenosis (CAS) who underwent DU imaging and DSA concluded that DU is similar to DSA in assessing high-grade CAS; however, it tends to lead to an overestimation of the degree of stenosis. Exclusion of 70%-99% angiographic stenosis with DU alone can be achieved with a sensitivity of 98% [45]. DU has been the procedure of choice in screening for CAS in the majority of the carotid trials to date [46]. Relevant diagnostic criteria and cut-offs for intervention have been reported by these trials with the NASCET and ECST criteria representing the most commonly used [47]. The recommended criteria, at least for the United Kingdom, are based on the NASCET method of grading carotid bulb disease. Key recommendations include recording peak systolic velocity (PSV) and end-diastolic velocity (EDV) in both internal and distal common carotid arteries; measuring all velocities at a Doppler angle of 45-60 degrees; the use of internal carotid PSV of >1.25 ms (-1) and >2.3 ms (-1) and a Peak Systolic Velocity Ratio of >2 and >4 to indicate $>50\%$ and $>70\%$ stenosis respectively; and the use of the St Mary's Ratio to grade $>50\%$ stenoses in deciles [47]. Regarding post-surgery or stenting stenoses, DU is also excellent in detecting recurrent disease with a sensitivity and specificity of greater than 95% compared to DSA [48]. The main advantage in using DU in assessing patients with CAS is the fact that it provides a dynamic image of the carotid plaque. High-risk plaques from symptomatic patients have been shown to demonstrate characteristics such as

intraplaque hemorrhage, higher lipid content, larger lipid core, less distance between lipid core and flow lumen, and less calcium compared to plaques from asymptomatic patients [49].

DU in Post-EVAR Surveillance and Endoleak Assessment

The role of DU in surveillance after endovascular aneurysm repair (EVAR) and the assessment of possible endoleak remains controversial [50]. EVAR offers the advantage of lower perioperative mortality and morbidity [51] but carries the cost of device-related complications such as endoleak, graft migration, graft thrombosis, and structural graft failure [52]. These mandate a lifelong surveillance. A low sensitivity of DU in detecting endoleak has previously been reported, in the range of 25% to 42% [53-56]. However, one study has reported that DU is better at determining the subsequent intervention strategy than CT alone in the case of endoleak [57]. Overall, studies comparing CDU with CT scan for investigation of post-EVAR complications have produced mixed results [25]. Newer DU imaging modalities aided by the administration of contrast may be more accurate at depicting endoleak, avoiding the need for radiation (MDCTA). A recent meta-analysis of plain and contrast enhanced DU including 25 studies (3,975 paired scans) compared DU with CT for all types of endoleak after EVAR. The pooled sensitivity was 74% and the pooled specificity was 94% for all endoleaks. Thirteen studies (2,650 paired scans) reported detection of types 1 and 3 endoleak by DU; the pooled sensitivity was 83% and the pooled specificity was 100%. The pooled sensitivity of contrast enhanced DU was 96% with a specificity of 85% (all endoleaks). For type 1 and 3 endoleaks the sensitivity and specificity of contrast enhanced DU were 99% and 100% respectively [25]. Current practices among centres vary; however, given the results of the aforementioned recent meta-analysis a surveillance programme using radiographs (serially) to assess for migration and DU with or without contrast can be considered as safe and is employed by several centres.

ABSTRACT

Colorectal surgery manages diseases of the small and large bowel, rectum, anal canal and pelvic floor. The colorectal surgeon undertakes a large array of minor and major, elective and emergency procedures. One of the main instruments in his quiver, aiding in the diagnostics of various diseases and conditions, are the radiological investigations. Plain radiographs have been used for many decades to assess patients with abdominal symptoms, but they have been replaced in the last years by more advanced techniques, such as computed topographies, magnetic resonance imaging and nuclear tests.

This chapter aims to introduce the reader to most of the radiological tests available to the colorectal surgeon today; some very specialized/specific tests will not be mentioned, as the authors believe that they are outside the aim of the book. Furthermore, we will look at specific diseases and pathologies and how radiological findings aid in their management and treatment.

ANATOMY OF THE COLON AND RECTUM

The colon frames the abdomen and is surrounded by fat. It has five distinguished portions: the cecum, the ascending, transverse, descending and sigmoid colon and the rectum, with a length of 1.5 m from the ileocecal valve to the distal rectum. Three longitudinal bands, the teniae, approximately 8 mm wide, run the length of the colon on its outer surface and merge in the appendicocolic and the rectosigmoid junction. Between the teniae, prominent

* Corresponding Author's Email: mpramateftakis@hotmail.com.

saculations are formed known as the haustrae. Along the teniae run epiploic appendices, which are small packets of fat. Their size depends on the nutritional status of the individual. The calibre of the colon varies from a 9 cm diameter in the cecum, to 6 cm in the transverse colon and with a slightly smaller diameter in the descending and sigmoid colon, with a large variation in the caliber of the rectum. The thickness of the wall is less than 3 mm; when the bowel is distended it is barely seen.

The rectum is bound by the sigmoid colon and the anus, extending 12 cm above the anal verge. Its proximal portion is located in the peritoneal cavity while the distal portion is extraperitoneal. The dentate line, extending for 5-10 mm in the anal canal, separates the rectal columnar epithelium from the anal squamous epithelium. At the rectosigmoid junction, the confluence of the taenia coli muscles form a surgically recognized line, at the level of the sacral promontory and the peritoneal reflection. The rectum is supplied by the inferior mesenteric and the superior and middle hemorrhoidal arteries. The proximal part is drained by the inferior mesenteric vein via the portal vein, while the distal part is drained by the internal ileac veins via the inferior vena cava. This venous drainage explains why cancers of the distal rectum usually form metastases in the lung, whereas proximal rectal cancers usually metastasize to the liver. Hemorrhoidal venous plexi, internal and external, are located on either side of the dentate line, causing hemorrhoids when dilated. Three valves of Houston project into the lumen, being normal folds in the mucosa, run up the length of the rectum in a spiral way. The internal anal sphincter is the thickening and continuation of the circular muscle layer of the rectum. The external sphincter is composed by the inferior portion of the levator ani muscle, the puborectalis muscle and the deep, superficial and subcutaneous external sphincter muscles. The wall of the rectum consists of five layers—the mucosa, the muscularis mucosa, the submucosa, the muscularis propria and the serosa—that are easily recognized in T2 weighted images at magnetic resonance imaging (MRI). On the MRI, one can also recognize the mesorectal fat and the fascia surrounding the rectum [1-4].

IMAGING

Plain Radiographs

Plain radiographs have always been a quick tool for assessment of bowel symptoms. 3 views are usually taken: The supine, which contrasts intra-abdominal organs and shows retroperitoneal air. The decubitus, which displays gas distribution in the bowel loops.

The erect chest radiograph, which detects extraluminal intra-abdominal air, presenting as free air under the diaphragm. Plain radiographs of the abdomen in these three positions can reveal signs of obstructive or paralytic ileus with air fluid levels and bowel distention (Figure 1), free peritoneal or retroperitoneal air (Figure 2), as well as stones (such as appendicoliths), calcifications and foreign bodies. Furthermore, it can aid in the diagnosis of pseudo-obstruction, volvulus or colitis.

The best indication for a plain abdominal x-ray is a patient with symptoms of bowel obstruction, and it aids in the differentiation between small and large bowel obstruction. As a rule of thumb, the more distal the obstruction, the more dilated loops of small bowel can be seen. In case of large bowel obstruction, the appearance and gas distribution may be similar to

the one of small bowel. Small bowel loops have plicae circulares, which traverse the whole lumen diameter, whereas colon shows haustral markings that do not reach the opposite wall.

Figure 1. Abdominal x-ray showing typical air-fluid levels of small bowel loops in the central and lower abdomen, suggestive of small bowel obstruction.

Figure 2. Erect chest radiograph, displaying free intraabdominal air under the diaphragm, suggestive of perforation of intraabdominal viscus.

Contrast Studies

Barium enema or air enema examination has acted as the gold standard examination in diagnosis of large bowel diseases for many years. In recent years, it has been replaced by more advanced techniques such as computed tomography (CT) and MRI. These tests allow a more precise evaluation of mucosal or submucosal, benign or neoplastic lesions, which is of course aided by the use of endoscopy. Cross sectional imaging can show the entire length of the large intestine and the thickness of the bowel wall, with the complementary evaluation of

the surrounding tissues, the extent of the disease, the origin and the internal composition of the lesion [3, 4].

Two different forms of contrast agents have been used to visualize colonic abnormalities: Barium studies and water-soluble contrast studies. Furthermore, one can differentiate between single and double contrast studies. Single contrast studies, using one medium to detect colonic lesions, are limited to only lesions of larger size. Double-contrast studies use gas as the second medium, which creates a thin coating on the mucosal surface allowing visualization of smaller lesions. Good bowel preparation is essential for any contrast study.

Double contrast barium enemas are simple and risk-free to perform and can rule out gross pathologies. They are obviously less accurate than endoscopy, as they can miss smaller lesions, there is no direct visualization and no biopsy possibility. Contrast enemas are, nevertheless, extremely useful in case of failed or incomplete colonoscopies, where the patient has undergone bowel preparation already.

In the case of a suspicion of perforation, barium as a contrast needs to be avoided. In this case, a water-soluble contrast such as Gastrografin® or Urografin® has to be used. When given orally, these agents also have a therapeutic effect on small bowel paralytic ileus. Contrast agents can also be used to visualize anastomotic integrity in colorectal or coloanal anastomoses and to visualize ileoanal pouches, giving information about the pouch's form, function and volume [5, 6].

Computed Tomography

Computed tomography (CT) is one of the commonest investigations undertaken by surgeons on a daily basis. CT takes cross-sectional images of the body and the computer software combines them to create tomographic images of the organ / body area of interest. Conventional CT scanning takes images at 1-cm intervals, whereas modern spiral CT scanners produce a continuous image as the camera rotates around the patient. Accurate CT imaging requires the opacification of the gastrointestinal tract and the vessels with the use of contrast medium, which is given as a bolus at the beginning of the investigation. CT is extremely useful in identifying postoperative complications but is also used in the investigation of non-specific abdominal symptoms and the staging of colorectal cancer. Images are obtained in two phases: the hepatic arterial and the portal venous phase. The radiologist analyzes the contrast behavior in various phases and concludes on the presenting pathology. Staging of colorectal cancer using CT includes assessment of the liver, grading of lymphadenopathy and assessment of possible intraperitoneal disease.

CT Colonography

CT colonography is also known as a virtual colonoscopy. Its accuracy is higher than that of the conventional CT, but the patients require full bowel preparation as for colonoscopy. Furthermore, they are exposed to radiation, even though there is no evidence that this radiation induces additional carcinogenesis. It is a good solution in patients too frail or unwell to undergo colonoscopy. The use of faecal tagging (with agents such as meglumine ioxithalamate) coats any residual bowel contents not cleared by the laxatives and allows the

radiologist to subtract remaining faeces from the images, minimizing the risk of false positive results [7, 8].

Magnetic Resonance Imaging

MRI scanners use magnetic fields to acquire images of the body. Water molecules in tissues are used to create signals, translated into images. The radio-frequency emitted by the hydrogen atoms is measured by receiving coils. The contrast between various tissues is determined by the rate the hydrogen atoms return to their state of equilibrium. Contrast agents are given orally or intravenously.

Image contrast can be weighted to demonstrate different anatomical structures. Tissues return to their equilibrium states by the independent processes of T1 or T2 relaxation. T1-weighted images are better for assessing morphological information, whereas T2-weighted images are useful in detecting oedema and inflammation. MR Diffusion Weighted Imaging (DWI) measures the diffusivity of extracellular water. This is a very rapid acquisition which can identify active inflammation in inflammatory conditions of the colon and rectum, being equivalent to contrast enhanced MRI. [9-11].

MRI is a very important tool for the management of anorectal diseases, the two most important being low rectal cancers and perianal fistulas. MRI is used for the accurate staging of rectal cancer, leading to tailored case-guided treatment protocols. Similarly, the topography of complex perianal fistulas can be very well assessed by MRI, showing the exact location of tracts and abscesses, which can map the surgical exploration.

Scintigraphy (Radionuclide Imaging)

For scintigraphy, an isotope is administered within the body or a specific organ. A gamma-camera (also called a scintillation camera) picks up the radiation emitted by the isotope. Depending on the organ being scanned, the physician can choose a specific isotope. For example, thallium is preferred for cardiac stress tests, whereas technetium99m-sestamibi is used to detect parathyroid adenomas. In colorectal practice, GI bleeding can be detected by tagging red blood cells with Technetium99m and re-injecting them into the patient.

Positron Emission Tomography

Positron emission tomography (PET) produces a three-dimensional image of functional body processes. It studies metabolic activity in tissues. A low-dose radionuclide (tracer) is coupled with glucose and injected intravenously. The PET scanning system measures the photon emission of the tracer within the body and constructs a 3D-image. Because malignant tumors consume glucose faster than normal tissue, this can be displayed as a dynamic image. PET-CT is a hybrid technique utilizing the strengths of PET and CT. It is powerful in detecting disease recurrence and has become established in assessing response to oncological treatment [E].

Defecography

Defecography is a traditional imaging technique, evaluating the functional aspects of the anorectal region. Even though it can be used to define various pathologies, its main strength lies in the understanding of postoperative conditions. Following formation of an ileo-anal pouch, a low colo-anal anastomosis for a low rectal tumor or a stapled resection of a rectal doughnut during a STARR procedure, the defecogram can give answers to the new anatomical configuration and the efficiency of the pelvic floor work during defecation. After insertion of radiopaque contrast (most commonly paste) in the rectum, a patient is asked to defecate. This test will pick up poor emptying, poor contrast retention, rectal pockets and rectoceles, giving also the possibility of measuring their size. Furthermore, it can identify sinus tracts, strictures and ulcerations.

COLORECTAL DIAGNOSTICS

There are a number of mucosal and submucosal lesions, neoplastic or non-neoplastic, that can be identified and have to be differentiated in the wall of the colon and rectum. Neoplastic lesions include adenocarcinomas, dysplastic or carcinomatoid polyps, lipomas, carcinoid tumors, lymphomas, hemangiomas, gastrointestinal stromal tumors, metastases, as well as direct bowel invasion of extracolonic tumor and peritoneal carcinomatosis. Non-neoplastic lesions include lymphoid polyps and hyperplasia, vascular lesions, cystic lesions, hematomas, endometriosis, extrinsic impressions, and pre-sacral lesions. Imaging studies play an important role in differentiating neoplastic or non-neoplastic lesions, as well as in the evaluation of patients for screening and staging of colorectal cancer. Below we are mentioning the most common colorectal conditions a surgeon is faced with, and the radiological tests he has available, to aid him to the correct diagnosis.

INFECTIVE / INFLAMMATORY CONDITIONS OF THE COLON AND RECTUM

Appendicitis

Inflammation of the appendix vermiformis results in the commonest acute abdominal presentation in hospitals nowadays, namely appendicitis, which is expressed with right lower quadrant pain, fever and nausea/vomiting. Appendiceal lumen occlusion results in accumulation of fluid in the appendix with lumen dilatation (>6 mm), inflammation and ischemia with wall thickening of more than 2 mm. Furthermore, it can lead to stranding of the pericaecal fat, perforation and abscess formation (Figure 3). An appendicolith (a calcified deposit within the appendix) is detected in 25% to 40% of cases. CT is routinely used as the initial imaging modality in adults with suspicion of appendicitis, with high accuracy rates, while ultrasonography (US) is preferably used in children, young adults and pregnant women. At MRI, STIR (short tau inversion recovery) images and single shot T2 images can easily reveal fluid in the periappendicular fat and wall thickening respectively, whereas strong contrast enhancement and restricted diffusion is indicative of appendicitis. The latter can also provide information about abscess formation [2, 13-15].

Figure 3. 38 year old female with right lower abdominal pain and leucocytosis. CT shows appendiceal wall thickening, lumen dilatation, inflammation and stranding of the pericecal fat, suggestive of appendicitis.

Epiploic Appendagitis

Torsion or venous thrombosis of one of the appendices epiploicae can result in inflammation or ischemia of the appendix, with sudden focal abdominal pain. An oval, up to 4 cm, fatty paracolic lesion accompanied by mesenteric inflammation is seen on CT, with a central dot corresponding to the thrombosed vein [2, 15].

Typhlitis

Typhlitis, also known as neutropenic enterocolitis, describes the inflammation and often necrosis of the cecum, ascending colon and terminal ileum. It can lead to edema, wall thickening and subsequent perforation. Clinical symptoms include fever, diarrhea and pain in the right lower quadrant. It is most often seen in neutropenic patients usually due to chemotherapy for leukemia or lymphoma, in patients with aplastic anemia, AIDS, or following kidney transplantation. Ischemia, cytomegalovirus infection and neoplastic infiltration are the probable mechanisms of the inflammation. In CT, hypodense wall thickening due to submural edema and sometimes intramural air is seen, as well as fat stranding and intraperitoneal free fluid or air [2, 15] (Figure 4).

Figure 4. CT of a neutropenic patient following chemotherapy for leukemia. Ischemia of the cecum, hypodense wall thickening due to submural edema as well as fat stranding, suggestive of typhlitis.

Diverticulitis

Diverticulae represent small pouches of the colonic mucosa and submucosa through the muscular layers of the colonic wall, where the vessels pierce the muscularis, between the mesenteric and antimesenteric teniae. Diverticulosis corresponds to the presence of multiple diverticulae seen as air filled pouches, measuring from 2-3 mm to 2 cm. They are most commonly located in the sigmoid colon. Diverticulosis is a very common condition nowadays, mostly related to modern diet and lifestyle. Occlusion of the neck of the diverticulum results in inflammation, called diverticulitis. Findings of diverticulitis are very well seen in contrast enhanced CT, with or without oral contrast medium (Figures 5, 6a, 6b).

Figure 5. Diverticulosis. Non-inflamed pouches of the transverse and sigmoid colon.

(a)

(b)

Figure 6. CT scan of a patient with diverticulitis. Inflammatory pericolic fat stranding and enhancement, with perforation and presence of free air locally in the peritoneal cavity (6a) with excessive air in the subphrenic space (6b).

Diverticulitis can lead to localised perforation, pericolic inflammation with fat stranding and presence of free air in the peritoneal cavity or retroperitoneum. Differential diagnosis of right colon diverticulitis, even though uncommon, can be made from appendicitis with careful analysis of CT images. In a study by Padidar et al, CT differentiation is made between acute diverticulitis and colonic cancer. Diverticulitis causes fluid in the root of the sigmoid mesentery as well as engorgement of mesenteric vasculature, whereas in colon cancer enlarged pericolic lymphnodes are found. Coronal STIR MRI and axial T2 images, as well as contrast enhanced and diffusion images, can also diagnose diverticulitis and its complications [2, 7, 15, 16-20].

Radiation Colitis

Following radiotherapy, any part of the colon can be affected, with acute findings of wall thickening and fat stranding. Chronic radiation injury causes strictures and fistulas, and can present with increased pelvic fat and thickening of perirectal fibrous tissue. All findings are best appreciated on CT images [2].

Ischemic Colitis

Ischemic Colitis is a cause of abdominal pain most commonly in the elderly. Causative factors can be colonic hypoperfusion, trauma, tumor invasion and mesenteric vascular occlusion by thrombus or embolus. When hypovolaemia is the etiologic factor, ischemic changes can be seen in the border of main vascular territories, such as in the splenic flexure and the rectosigmoid.

(a)

Figure 7. (Continued).

(b)

Figure 7. Axial (7a) and coronal (7b) reformation in a patient with hypovolemia and ischemic changes in the small and large bowel. Symmetric wall thickening, double halo or target sign (hypodense submural edema and hyperdense intramural hemorrhage) that can be seen in the thickened wall.

(a)

(b)

Figure 8. Necrosis of the rectum and the sigmoid colon (8a) in an 80 years old man due to embolic disease in IMA, that is shown non-enhanced with extensive wall calcifications in (8b).

Figure 9. Presence of air in the mesenteric veins (9a) and portal vein (9b) due to bowel necrosis in a 79 years old patient.

When ischemia is suspected, CT evaluation of the colon can reveal diffuse or segmental circumferential, symmetric wall thickening with fold enlargement. The double halo or target sign, which can be seen in the thickened bowel wall, is due to hypodense submural edema and hyperdense intramural hemorrhage (Figures 7a, 7b). Thrombosis or embolic disease can easily be delineated by CT (Figures 8a, 8b), as well as the presence of intramural air or air in the mesenteric and portal veins (Figures 9a, 9b), a finding suggestive of bowel necrosis. Imaging of thrombosis or embolic disease, vasoconstriction, as well as aortic dissection relies mainly on CT or MRI angiographic techniques. MRI coronal STIR images can reveal the area of ischemic bowel with thickening of the wall and infiltration of the surrounding fat, while axial T2 images can be unremarkable. Patchy bowel enhancement in contrast enhanced MR images show the disturbed perfusion of the bowel wall. In conservatively treated patients, the colon can sometimes return to normal, with development of strictures of the involved segment [2, 16].

Infectious Colitis

Bacteria, fungi and viruses can cause infectious colitis that can affect any portion of the colon. The definitive diagnosis is given mainly by laboratory tests. CT, when utilized, reveals

bowel wall thickening with intramural diffuse or segmental edema, depending on the causative microorganism, with presence of pericolic inflammation and ascites [2].

Pseudomembranous Colitis

Antibiotic therapy, hypovolemia, chemotherapy or abdominal surgery can cause overgrowth of *Clostridium difficile*, which results in pseudomembranous colitis (secondary to the production of toxins). Associated symptoms include diarrhea, fever and abdominal pain. On CT, the colon is dilated with wall thickening due to edema and a visible target sign. Significant haustral thickening with oral contrast entrapment can be seen, known as the accordion sign. The wall thickening is irregular and shaggy as well as greater than the thickness observed in other inflammatory bowel conditions. Only in Crohn's disease is the amount of wall thickness as great as it is in pseudomembranous colitis but it is symmetric and homogeneous [2].

INFLAMMATORY BOWEL DISEASES (IBD)

The incidence of inflammatory bowel disease in the Western World has increased in the past 50 years up to 8–14/100,000 patients for ulcerative colitis (UC) and up to 6–15/100,000 patients for Crohn's disease (CD). It is continuing to increase worldwide. The occurrence in the pediatric population is 4.56 per 100,000 children [21-23].

The principal tools for diagnosis and evaluation of suspected inflammatory bowel disease are CT and MRI, although classic barium studies are still used with sometimes equivocal results. CT and MRI have the advantage of visualization of the bowel wall, adjacent structures, extra luminal disease and complications in both diseases. The imaging modalities of choice are CT and/or MRI, with similar sensitivities in diagnosing IBD, with the latter being more sensitive in the detection of strictures and fistulas. MRI is the preferred modality in children and young adults because of lack of ionizing radiation and the potential in differentiation of chronic from acute disease, especially with the use of Diffusion Weighted Imaging. Restricted diffusion correlates with the severity of IBD, being an indicator of severe complications such as bowel perforation and abscess formation [11, 16, 21-23].

Ulcerative Colitis

Ulcerative colitis occurs more frequently in men and it is a typically left sided, diffuse disease (colon and rectum). It rarely involves the right colon only and it extends in a continuous retrograde mode. Wall thickening, with a mean of about 7.8 mm, may be diffuse and symmetric in thickness (Figure 10). A low attenuation ring, like a halo sign, can commonly be seen in the thickened bowel wall, due to deposition of submucosal fat [2, 11, 21].

Figure 10. Ulcerative colitis: Diffuse and symmetric sigmoid wall thickening.

Crohn's Disease

CD occurs more frequently in women and it usually involves the right colon and small intestine with a mean wall thickening of about 11–13 mm that may be eccentric and segmental with skip regions. The thickened edematous bowel wall enhances strongly and homogeneously and it is accompanied by proliferation of mesenteric fat and mesenteric lymphadenopathy. (Figures 11, 12) Fibrofatty proliferation can also be seen in UC and in other inflammatory conditions of the bowel wall.

CT and MRI can visualize abscesses, strictures and fistulas as complications of CD. Abscesses can be confined to the bowel wall and pericolic fat, or can involve adjacent structures that can be drained under CT or US guidance. CD begins with aphthous ulcers that develop into strictures and fistulas. Fistulas can be enteroenteric, enterocutaneous, enterovesical, rectovaginal or perianal. They can be evaluated with MRI, as well as with CT performed after oral or rectal contrast administration. Fistulas are more frequent in patients with terminal ileal disease. Large bowel Crohn's disease can remain uncomplicated for years. The diagnosis of terminal ileitis mainly relies on MRI, coronal STIR and axial T2 images. Lymphadenopathy is easily depicted with DWI. [2, 11, 15, 19-23].

Figure 11. Transverse CT image of a young patient with Crohn's disease. Thickened and edematous bowel wall at the ileocecal valve and terminal ileum.

Figure 12. Saggital reformative CT image of a patient with Crohn's disease in the ileocecal valve, cecum and ascending colon with asymmetrically thickened wall.

COLORECTAL CANCER

Computed Tomography

CT enterography and CT colonography provides important information about TNM staging in preoperative assessment of colon cancer, as well as information about vascular anatomy. Standard colon window settings should be used, with a width of 1,500 Hounsfield Units (HU) and a level of -200 HU, as well as abdominal window settings with a width of 440 HU and a level of 20 HU.

The ability of CT colonography to demonstrate lesions >10 mm is very good. On the contrary small polyps, adenomas or lipomas < 5mm are impossible to be demonstrated, while lesions of 6-9 mm are demonstrated with less sensitivity compared to the larger ones. Colorectal carcinogenesis occurs after a series of mutations, as a polyp progresses from adenoma to adenocarcinoma. Larger polyps more likely harbor dysplasia or malignancy compared to sessile polyps, whereas pedunculated lesions do not usually harbor malignancies. An attempt should be made for lesions 6-9 mm to be removed colonoscopically. Larger polyps may be removed endoscopically but may require surgery, given the technical difficulties due to their size.

Flat colorectal lesions are difficult to identify at CT colonography, as are small or larger lesions that are hidden behind folds. Large carcinomas are either fungating masses or areas of mucosal irregularity homogeneously enhanced, that in a 5% of cases can be accompanied by a synchronous carcinoma elsewhere in the colon (Figure 13).

Figure 13. Sigmoid cancer: Mucosal irregular thickening of the sigmoid colon and stranding of the pericolic fat.

Lymphnode metastases from colorectal cancer often present with calcifications, as do liver metastases in about 10%-30% of cases.

Liver metastases are hypoattenuating lesions in non-enhanced CT scans, with rim enhancement in the arterial phase and heterogeneous enhancement in portal venous phase. Most of the lesions depicted in the lung are benign unless they are multiple and the primary tumor is located in the distal part of the rectum [3, 24, 25].

Magnetic Resonance Imaging

MRI, MR enterography and MR colonography with the use of DWI and T2 imaging can also give important information about TNM staging in colon but especially in rectal cancer. MRI has proven to be priceless in the analysis of rectal cancers, where one can evaluate intraluminal and extraluminal extent, mesorectal involvement, and assessment of tissues beyond the mesorectal fascia.

MRI can evaluate the integrity of rectal wall layers, as they are very well delineated on T2WI, with visualization of the rectal mucosa and muscularis propria by low signal intensity, the submucosa and mesorectum by high signal intensity and the mesorectal fascia by linear low signal intensity, with a high accuracy in T staging.

It is very important for the mesorectal fascia to be intact, as it determines the circumferential resection margin for a total mesorectal excision. The frequency of recurrence is 19%-22% in patients with positive circumferential resection margin, compared to 3%-5% in patients with negative circumferential resection margin. It is also frequently associated with distant metastatic disease.

Diffusion weighted imaging has high accuracy in depicting colorectal cancer, with a 90.9% sensitivity and 100% specificity. The cellularity of malignant tumors is greater than that of normal tissue and appears hyperintense in DWI with restricted diffusion, and hypointense in apparent diffusion coefficient (ADC) maps with low values (Figures 14a-14c). Possible fibrotic and desmoplastic tissue can be differentiated from tumor infiltration with low signal intensity in both DWI and ADC maps.

Figure 14. MRI of a rectal carcinoma shown in 14a with intermediate signal intensity on T2 weighted image, that infiltrates the mesorectal fat (shown with high signal) and its distance from mesorectal fascia (shown with low signal) is more than 5 mm. It is accompanied by two enlarged round lymphnodes with an intermediate signal intensity. The primary tumor and the metastatic lymphnodes show restricted diffusion on DWI with high signal intensity in image 14b with low apparent diffusion coefficient values and low signal intensity shown in image 14c (ADC values of the primary tumor and the metastatic lymphnodes of about $0.98 \times 10^{-3} \text{ sec/mm}^2$).

Criteria in predicting nodal involvement is a cutoff in size of 10 mm of a round lymphnode as well as the border irregularity, mixed signal intensity and T2* low signal of ultra-small iron particle uptake from the metastatic lymph node. Metastatic lymphnodes show restricted diffusion on MRI DWI with low ADC values (ADC values by using a threshold of $1.0\text{--}1.38 \times 10^{-3} \text{ sec/mm}^2$), that is a good indicator of cancer cell viability and it is also used to show changes before and after chemo-radiation therapy in the assessment of the primary tumor and the lymphnodes [4, 25–28].

Recurrence of rectal cancer is best appreciated with MRI, being the modality of choice for follow up, evaluating recurrence patterns and findings of unresectability [27].

Positron Emission Tomography – Computed Tomography

PET-CT better delineates primary, lymphnode and metastatic disease in colorectal cancer for preoperative staging, and it is recommended for identification of recurrent disease. PET-CT colonography is recommended in patients with obstructive colorectal cancers [20].

Most of the times, a combination of CT, MRI and PET-CT is needed for accurate preoperative tumor staging.

Chapter 83

THE ROLE OF IMAGING IN BREAST SURGERY

Vasileios N. Papadopoulos*, MD, PhD

1st Surgical Propedeutic Department
Medical School of Aristotle's University of Thessaloniki, Greece

ABSTRACT

During the past decades, there has been significant improvement in the equipment and image-recording systems for breast diseases and for investigation of the axilla. In addition to providing better images, these developments have resulted in a significant reduction in radiation dose. Screening mammography is used to detect unexpected breast cancer in asymptomatic women since the 1960s. Specific mammographic features that suggest a diagnosis of breast cancer include a solid mass with or without stellate features, clustered microcalcifications, and asymmetric thickening of breast tissues. Imaging of the breast has evolved from mammography alone to mammography with adjunctive modalities that primarily include ultrasound and magnetic resonance imaging (MRI scan). Until recently, ultrasound and MRI have functioned as problem-solving tools and have been used to help to diagnose a mammographically and/or clinically detected abnormality such as a breast mass or nipple discharge. As these modalities have improved technologically and immense clinical experience has been acquired, so have their roles expanded from diagnostic tools to potential screening tools as well. Ultrasound has many uses that relate to the evaluation of breast masses. Sonographic guidance is used frequently for the direction of percutaneous breast biopsies and to investigate the status of axillary lymph nodes in breast carcinoma. MRI was initially used for the evaluation of implants, but it now has a variety of roles associated with the evaluation of tumors. With a dedicated breast coil and contrast enhancement, MRI has been of great value in identifying the extent of breast carcinoma and contributing to better patient management plan. A breast positron emission tomography (PET) scan is another imaging modality of the breast that uses a radioactive substance (F-18-fluoro-2-deoxy-D-glucose - FDG). Whole-body FDG-PET can detect distant metastatic disease to the lymph nodes, the soft tissues, viscera, and bone. PET scan is also used to assess whether metastatic breast cancer is responding to treatment. After breast biopsy, scarring and distortion of breast tissue occur, making subsequent evaluation by mammography difficult. Thus,

* Corresponding Author's Email: bnpap@med.auth.gr.

other imaging techniques, such as MRI, and PET, are being increasingly used for characterizing lesions in the breast. All imaging techniques now used in breast surgery continue to be modified and improved to maintain optimum image quality that enhances interpretation skills of the clinicians and radiologists.

INTRODUCTION

Over the past decades the use of breast imaging has increased, with more emphasis being placed on ultrasound (US) and magnetic resonance imaging (MRI) than ever before. While mammography remains the front line in screening and first-time diagnosis, US and MRI allow a more accurate characterization of lesions and symptomatic findings. [1, 2] The number of breast cancer detections has increased, as have the instances of surgical breast interventions. In order to detect the abnormal changes in the breast, breast surgeons and breast imagers must be also familiar with the normal findings of the postsurgical breast. The techniques of biopsy, implantation, and reconstruction have also evolved, changing the breast imaging findings as well [1-4].

The progress of technology has enabled control of the status of breast and axillary lymph nodes with many imaging methods. The main methods currently used are:

- 1) Ultrasonography,
- 2) Mammography,
- 3) MRI,
- 4) CT scan,
- 5) Pet scan.
- 6) Scintimammography

1. ULTRASONOGRAPHY (US)

In breast US, sound waves are emitted into the breast, and an image is created by the returning sound waves received by the ultrasound detector. As there is no ionizing radiation, it is useful in young and pregnant women. Advantages of breast ultrasound include the ability to better characterize the composition of breast parenchyma, and to investigate the presence of lesions - nodules and easily recognize compact or cystic texture and the size, shape, perfusion, elements that distinguish and characterize a lesion as benign or malignant. In suspected lesions enable biopsy under the guidance of ultrasound. In axillary cavity status information of nodes there is substantial and ultrasound also checks outside of the lymph nodes status of vessels (arteries, veins) (Figure 1), nerves, connective tissue and sometimes ectopic mammary gland. The axillary lymph nodes are divided into three levels based on their anatomic relationship to the pectoralis minor muscle: level I nodes are inferior to the pectoralis minor muscle, level II nodes are posterior to the muscle, and level III nodes are medial to the muscle [5].

The main groups of axillary lymph nodes include: The group of axillary vein lymph nodes, the group of scapular, the central group, the lymph nodes of Rotter (between the pectoral muscles) the team of the pectoralis major muscle, and the group of subclavicular

lymph nodes. Skandalakis JE et al., [6], report that the axillary drainage of the breast includes an average number of 35.3 nodes in 6 groups.

Group 1. External mammary nodes (average number of 1.7 nodes), also called the anterior pectoral nodes. These lie along the lateral edge of the pectoralis minor, deep to the pectoralis major muscle, along the medial side of the axilla following the course of the lateral thoracic artery on the chest wall from the second to the sixth rib. Deep to the areola there is an extensive network of lymphatic vessels, the so-called subareolar plexus of Sappey. In the circumareolar region, large lateral and medial trunks receive much of the lymph from the breast parenchyma. The lateral trunk receives collaterals from the upper half of the breast and the internal trunk drains the lower part of the breast. These vessels pass around the lateral border of the pectoralis major muscle to reach the external mammary nodes.

Figure 1. Axillary vessels in color US.

Group 2. Scapular nodes (average number of 5.8 nodes). These lie on the subscapular vessels and their thoracodorsal branches. Lymphatics from these intercommunicate with intercostal lymphatic vessels.

Group 3. Central nodes (average number of 12.1 nodes). This is the largest group of lymph nodes; they are the nodes most easily palpated in the axilla, because they are generally larger in size. They are embedded in fat in the center of the axilla. When these nodes enlarge, they can compress the intercostobrachial nerve, the lateral cutaneous branch of the second or third thoracic nerve, causing accompanying pain.

Group 4. Interpectoral nodes (Rotter's nodes) (average number of 1.4 nodes). These lie between the pectoralis major and minor muscles. Often there is a single node. They are the smallest group of axillary nodes and will not be found unless the pectoralis major is removed.

Group 5. Axillary vein nodes (average number of 10.7 nodes). This is the second largest group of lymph nodes in the axilla. They lie on the caudal and ventral surfaces of the lateral part of the axillary vein.

Group 6. Subclavicular nodes (average number of 3.5 nodes). These lie on the caudal and ventral surfaces of the medial part of the axillary vein [6].

Second only to mammography in frequency of use for breast imaging, ultrasonography is an important method of resolving equivocal mammographic findings, defining cystic masses,

demonstrating the echogenic qualities of specific solid abnormalities, and greatly facilitates the recommendations for follow-up or further evaluation of the patient [4].

Figure 2. Breast cyst on ultrasound.

Figure 3. Solid tumor of left breast in US.

On ultrasound examination, breast cysts are well circumscribed, with smooth margins and an echo-free center (Figure 2). Benign breast masses usually show smooth contours, round or oval shapes, weak internal echoes, and well defined anterior and posterior margins. Breast cancer characteristically has irregular walls but may have smooth margins with acoustic enhancement (Figure 3,4).

Ultrasonography is used to guide fine-needle aspiration biopsy, core-needle biopsy, and needle localization of breast lesions (Figure 5). Its findings are highly reproducible and it has a high patient acceptance rate, but it does not reliably detect lesions that are less than one cm in diameter. In patients with breast cancer, evaluation of axillary lymph nodes (ALNs) is very important, as it is a powerful prognostic indicator and decisive factor for developing a breast cancer treatment plan. Traditionally, axillary lymph node dissection (ALND) has been used for nodal staging, but currently use of sentinel lymph node biopsy (SLNB) has increased in frequency as an alternative procedure for patients with early breast cancer. Importantly, while SLNB has decreased the morbidity of staging by avoiding unnecessary ALND, it is also an invasive method, and it may be an inconvenience for some patients to undergo a two-stage surgical procedure. Therefore, it would be of great clinical benefit if a reliable imaging method or minimally invasive procedure for determining ALN status were available. If there

were no evidence of ALN metastasis in preoperative staging, SLNB would be performed. On the other hand, patients with ALN metastasis found on preoperative staging would directly undergo ALND or neoadjuvant chemotherapy [7, 8].

Figure 4. Right breast tumor (BIRADS 5) in US.

Figure 5. Needle biopsy with US guidance.

In terms of preoperative evaluation for ALN metastasis, physical examination has low sensitivity, between 35 and 82% and specificity ranges from 73% to 97%. Ultrasonography (US) of ALN has superior diagnostic accuracy in many studies when combined with US-guided fine-needle aspiration biopsy (US-FNA) of sonographically suspicious lymph nodes. The sensitivity and specificity of US examination in the evaluation of ALN metastasis have been reported to be 36–92 and 69–100%. Addition of US-FNA to axillary US may increase specificity to 93–100% [7-11].

Figure 6. Metastatic axillary lymph node in US.

Figure 7. Metastatic axillary lymph node in US.

The combination of axillary US and US-FNA is useful in preoperative work-up of breast cancer patients and is valuable in planning proper management of breast cancer patients.

Ultrasonography can also be utilized to image the regional lymph nodes in patients with breast cancer (Figure 6, 7, 8). On ultrasound, lymph nodes have a characteristic appearance. They are very well defined and oval or lobular with mixed echogenicity (Figure 9). The cortex is hypoechoic, and the fatty hilum is hyperechoic. Abnormal nodes may lose this appearance and be more rounded and poorly margined. Intramammary lymph nodes have an appearance similar to that of axillary nodes; namely, they are well defined, mixed density or medium to low density, round, ovoid, or reniform nodules with a fatty notch or center. Intramammary nodes can be found throughout the breast but most commonly are located in the middle- to upper-outer aspect of the breasts [12].

Ultrasound is an essential component in the workup of a palpable or mammographically evident lesion. It is also highly specific, relatively inexpensive, and widely available. Sonography can be used for a targeted region of the breast. Poor visualization of

microcalcifications, which are often a sign of malignancy, is the ultrasound's main disadvantage. Although sonography cannot definitely differentiate benign from malignant solid masses, the correlation of a circumscribed mass that has not enlarged on mammography and benign sonographic characteristics can be used to follow rather than biopsy a nonpalpable lesion. Malignant sonographic criteria include spiculation, a taller-than-wide shape, angular margins, shadowing, branching pattern, hypoechoicity, duct extension, and microlobulation. The presence of these features, even in the face of a relatively circumscribed mass on mammography, should prompt biopsy [4, 12].

Figure 8. Multiple vessels in metastatic axillary lymph node in US.

Figure 9. Normal axillary lymph node in US.

Pneumocystography also may be performed at the time of aspiration to outline the internal aspect of the cyst wall. When sonography demonstrates a complicated cyst (imperceptible wall, acoustic enhancement, and low-level echoes) or a cluster of microcysts, the likelihood of malignancy is very low. Cystic masses with thick walls, thick septae, or an

intracystic solid component or predominately solid masses with cystic foci are categorized as complex cysts. Complex cysts may be malignant, and biopsy is warranted. Papillomas and intracystic papillary carcinomas may develop within a cyst. Invasive papillary carcinomas tend to present as multiple, relatively well-defined masses. If a cyst contains an intracystic lesion, lobulation or slight irregularity of the wall may be seen on mammography. On pneumocystography, papillary lesions are seen as a polypoid filling defect within the cyst cavity [12, 13].

1.1. US Report Organization

According to the Guidelines of “The American College of Radiology (ACR)” in ACR BI-RADS® Atlas 5, the report should be concise and organized using a structure such as that provided in Table 1.

Table 1. Report organization

	Report Structure
1.	Indication for examination
2.	Statement of scope and technique of breast US examination
3.	Succinct description of the overall breast composition (screening only)
4.	Clear description of any important findings
5.	Comparison to previous examination(s), including correlation with physical, mammography, or MRI findings
6.	Composite reports
7.	Assessment
8.	Management

The indication for examination, relevant clinical history, and pertinent risk factor information should be clearly stated. If the study is performed for follow-up of a specific mass or area of concern, this should be described. The dates of any comparison examinations should be specified. When a specific sonographic finding is documented by recording a complete set of images, the longest horizontal dimension should be reported first, followed by the vertical measurement, and the orthogonal horizontal dimension last. Multiple simple cysts or a combination of multiple simple and complicated cysts need not be reported individually. If any lesions have been biopsied previously, this should be noted together with the prior biopsy results, if known. Correlation of any clinical, mammographic, and MRI findings with the sonographic findings should be specifically stated in the report. For diagnostic evaluations involving US characterization of mammographic abnormalities or confirmation of a mass suspected but not delineated mammographically, a single report integrating the two modalities will clearly communicate a final assessment based on the highest likelihood of malignancy and appropriate management recommendations. Consistent use of BI-RADS® descriptors for US, as for mammography and MRI, helps in lesion assessment and clarifies communication with physicians and patients. Also, structured, software-based reporting should be based on BI-RADS® terminology. For coding and reimbursement, it is considered the advisability of splitting the report combining the findings of two or more concurrently performed imaging modalities or procedures into specific sections or paragraphs, one for each

type of examination. However, a single assessment and recommendation for patient management should reflect integration of the findings from all of the imaging studies. It is important that an assessment based on specific findings needing most urgent attention will have the greatest clinical utility.

1.1.1. Indication for Examination

The reason for performing the examination should be stated briefly at the beginning of the report. The most common indications for breast US are confirmation and characterization of a palpable mass or mammographic or MRI abnormality, guidance of interventional procedures and as the initial imaging technique for young, pregnant, or lactating patients. Additional applications are listed in the ACR Practice Guideline for the Performance of the Breast Ultrasound Examination and include the extent of disease evaluation supplementing mammography in high-risk women who are not candidates for breast MRI or who have no easy access to MRI, and in breast imaging practices that provide the service, supplementary whole-breast screening in order to increase cancer detection in asymptomatic women with mammographically dense breasts.

1.1.2. Statement of Scope and Technique of Breast Us Examination

The scope of examination and technique used should be stated, for example, whether the examination was directed or targeted to a specific location, or whether it was performed for supplementary screening. It is important, since US is a real-time examination, to indicate who performed the examination (sonographer, sonographer and physician, physician alone) or whether an automated whole-breast scanning system was used. If a lesion was evaluated with color or power Doppler or with strain or shear-wave elastography, observations relevant to the interpretation should be reported. In certain situations, it may be beneficial to describe the position of the patient during the examination (e.g., “The breasts were imaged in both supine and lateral decubitus position.” or “The patient was imaged in seated position, the position in which she feels the left breast thickening best.”).

1.1.3. Succinct Description of the Overall Breast Composition (Screening Only)

Tissue composition patterns can be estimated more easily in the large field of view (FOV) of automated US scans but can also be discerned in the small FOV of a handheld US scan. The three US descriptors for tissue composition are “homogeneous background echotexture-fat,” “homogeneous background echotexture-fibroglandular,” and “heterogeneous background echotexture” (Table 2) correspond loosely to the four density descriptors of mammography and the four fibroglandular tissue descriptors of MRI. At US, breast tissue composition is determined by echogenicity. Subcutaneous fat, the tissue relative to which echogenicity is compared, is medium gray and darker than fibroglandular tissue, which is light gray. Heterogeneous breasts show an admixture of hypoechoic and more echogenic areas. Careful real-time scanning will help differentiate a small hypoechoic area of normal tissue from a mass.

Table 2. Breast tissue composition patterns

	Tissue composition
a.	Homogeneous background echotexture-fat
b.	Homogeneous background echotexture-fibroglandular
c.	Heterogenous background echotexture

1.1.4. Clear Description of Any Important Findings

The description of important findings should be made, in order of clinical relevance, using lexicon terminology, and should include:

- a) Characterization of a mass using the morphological descriptors of shape, margin, and orientation. Note should be made of the lesion’s effect on the surrounding tissue, such as architectural distortion. Feature categories, such as posterior features and echogenicity, and techniques, such as color or power Doppler and elastography, may contribute information to the analysis, but only pertinent positives need to be described. Recognition of special case findings, such as simple and complicated cysts, clustered microcysts, intramammary lymph nodes, and foreign bodies, should simplify interpretation. In reporting screening examinations in asymptomatic women, as in mammography, characteristically benign findings may be reported (assessment category 2), but it is not obligatory, and the appropriate assessment would then be negative (assessment category 1).
- b) For important findings, lesion size should be given in at least two dimensions; three dimensions are preferable, especially if the volume of a mass is compared with one or more previous examinations. It is not necessary to report the measurements of every small simple cyst, and if numerous cysts are present, especially in both breasts; location and measurements of the largest cyst in each breast will suffice.

If a mass is measured, images should be recorded with and without calipers. Marginal characteristics are one of the most important criteria to be applied in assessing the likelihood of malignancy of a mass, and, particularly with small masses, caliper markings may obscure the margin, hindering analysis.

- c) Location of the lesion(s) should be indicated using a consistent and reproducible system, such as clock-face location and distance from the nipple. When more than one mass or abnormality is located in the same scan frame or in the same locale, measurement of the distance from the skin to the center of the mass or its anterior aspect may help to differentiate one lesion from another. This measurement may be particularly useful when one mass is singled out for biopsy and others are depicted in the field.

1.1.5. Comparison to Previous Examination(s), Including Correlation with Physical, Mammography, or MRI Findings

Breast US should be correlated with physical findings, mammography, MRI, or other imaging studies, if performed. If no statement of comparison is included in the US report, it will be assumed that no comparison was made. Note that some report templates include a

“comparison” heading, in which the word “none” (if appropriate) may be entered. When correlating US findings with those seen at mammography and/or MRI, the operator performing handheld scanning should correlate the size and location of lesions and match the type and arrangement of tissues surrounding the lesion in order to reduce the likelihood of misregistration (identifying a different lesion or lesions at different imaging modalities). In doing this, allowance for positional changes should be made going from upright with mammography and prone with MRI to supine or supine-oblique with US. If it is determined that a sonographic finding corresponds to a palpable abnormality, or to a mammographic or MRI finding, this should be stated explicitly in the US report. If the US finding is new or has no correlate, this should also be stated in the report.

If the US examination was performed as part of a surveillance protocol to assess a previously identified finding, or if the finding was reported on a previous examination, the current report should describe any changes. An increase of 20% or more in the longest dimension of a probably benign solid mass within 6 months may prompt biopsy. An increase of only 1–2 mm in lesion size may be related to differences in scanning technique or patient positioning.

1.1.6. Composite Reports

When more than one type of examination is performed concurrently (on the same day), it is preferable that the examinations be reported together. The findings for each examination should be described in separate paragraphs with an overall assessment and management recommendations for the combined examinations.

In general, when the assessments for two examinations differ, the overall assessment (and concordant management recommendations) should reflect the more abnormal of the individual assessments (whatever management is expected to come first, supplemented by likelihood of malignancy), according to the following hierarchy of increasing abnormality: category 1, 2, 3, 6, 0, 4, 5 (Table 3.).

Table 3. Abnormality hierarchy

BI-RANDS Assessment category	Degree of Abnormality
1	Lowest
2	
3	
6	
0	
4	
5	Highest

Exceptions to this rule occur when the characteristically benign features of a given imaging finding on one examination supersede the less specifically benign features of the same finding on the other examination. An example is that of a partially circumscribed, non-calcified mass at mammography, superseded by simple cyst at US.

1.1.7. Assessment

The report should conclude with a concise summary of pertinent US findings with a final assessment using BI-RADS® US categories 1–6 and the phrases associated with them.

If report of a US examination is integrated with that of a concurrently performed mammography examination, the combined final assessment should reflect the highest likelihood of malignancy assessed at the two examinations. Clear and consistent communication is a goal that can be achieved for breast US by using the same assessment categories and similar wording described in the BI-RADS® Mammography section (Table 4).

In some cases, the interpreting physician may render an incomplete assessment (category 0) in order to request additional examination(s), such as mammography, comparison with previous but currently unavailable examinations, or additional physician-performed real-time scanning after either a sonographer-produced, real-time or automated whole-breast screening US examination.

Table 4. BI-RADS® classification

BI-RADS® Category Descriptive Recommendation

0	Incomplete - Needs further evaluation (Additional views, ultrasound, comparison with old films)
1	Negative - Routine annual screening
2	Benign - Routine annual screening
3	Probably benign - Short interval follow-up mammography
4	Suspicious - Biopsy should be considered
5	Highly suspicious - Appropriate action/biopsy
6	Proven malignancy - Appropriate action

1.1.8. Management

Management recommendations should be included in every report. Clear recommendations should be made as to the next course of action. Recommendations may include routine age-appropriate screening, surveillance imaging for a probably benign mass, annual follow-up after percutaneous or surgical biopsy, and clinical management. If an imaging-guided interventional procedure is recommended, the type of imaging for the procedure might also be suggested, for example, stereotactic, US, or MRI guidance.

2. MAMMOGRAPHY

During the last decades convincing evidence has emerged that mammographic screening has contributed to a significant reduction in breast cancer mortality. Mammographic screening is especially important in the diagnosis of early-stage breast cancer, which relies primarily on nonpalpable mammographic abnormalities for detection (Figure 10, 11, 12). Ductal carcinoma in situ (DCIS) now accounts for approximately 20–30% of mammographically detected cancers. Current US Preventive Services Task Force (USPSTF) guidelines recommend against routine screening mammography in women aged 40–49 years [14].

Mammography has evolved from more dedicated equipment and industrial film, through dedicated film-screen mammography, and now to full-field digital mammography. Factors that affect the image quality include equipment, image-recording system, processing, compression of the breast, and the technologist's skill in positioning the patient. Adherence to strict quality assurance guidelines is critical in mammography to maintain optimum image quality.

Once the mammographic images are presented to the radiologist for interpretation, an approach to the analysis and interpretation defines how lesions are identified and how they are described and managed. The assessment and description of the mammographic findings are defined in a standardized method known as the Breast Imaging Reporting and Data System (BI-RADS®) (Table 4).

Figure 10. Right breast tumor in mammography.

Figure 11. Left breast tumor in mammography.

Figure 12. Metastatic axillary lymph nodes in mammography with no evidence of primary breast cancer.

BI-RADS® was developed by the American College of Radiology in the mid-1990s and includes a nomenclature for lesion description and overall assessment. BI-RADS® incorporates three basic components: (a) a description of the parenchymal density, (b) specific lesion descriptions for masses, calcifications, and other findings, and (c) an overall assessment or management recommendation for the patient. The use of this lexicon is ideal: The terms are standardized, and the correct use of the terms to describe an abnormality is helpful to the radiologist to correctly manage each case. The use of the standardized terminology and the requirement for an overall assessment are also very helpful for communication of the findings to the referring surgeon [12].

Mammogram reports will also include an assessment of breast density. BI-RADS® classify breast density into 4 groups:

1. The breasts are almost entirely fatty (Figure 13). The breasts contain little fibrous and glandular tissue, which means the mammogram would likely detect anything abnormal.
2. There are scattered areas of fibroglandular density (Figure 14). There are a few areas of fibrous and glandular tissue in the breast.
3. The breasts are heterogeneously dense, which may obscure small masses (Figure 15). The breast has more areas of fibrous and glandular tissue that are found throughout the breast. This can make it hard to see small masses.
4. The breasts are extremely dense, which lowers the sensitivity of mammography (Figure 16). The breast has a lot of fibrous and glandular tissue. This may make it harder to find a cancer that may be present, as it can blend in with normal breast tissue.

Figure 13. The breast is almost entirely fatty containing little fibrous and glandular tissue (Group 1).

Figure 14. There are scattered areas of fibroglandular density (Group 2).

Figure 15. The breast is heterogeneously dense, which may obscure small masses (Group 3).

Figure 16. The breast is extremely dense, which lowers the sensitivity of mammography (Group 4).

The fourth edition of BI-RADS®, unlike previous editions, indicated quartile ranges of percentage dense tissue (increments of 25% density) for each of the four density categories, with the expectation that the assignment of breast density would be distributed more evenly across categories than the historical distribution of 10% fatty, 40% scattered, 40% heterogeneously, and 10% extremely dense. However, it has since been demonstrated in clinical practice that there has been essentially no change in this historical distribution across density categories, despite the 2003 guidance provided in the BI-RADS® Atlas. The absence of change in clinical practice of the assignment of breast density across categories may reflect the reality that a few coalescent areas of dense tissue may be present in breasts with as little as 10% dense tissue, whereas primarily fatty areas may be present in breasts with as much as 90% dense tissue. The fifth edition of BI-RADS® no longer indicates ranges of percentage dense tissue for the four density categories. This is done to emphasize the text descriptions of breast density, which reflect the masking effect of dense fibroglandular tissue on mammographic depiction of non-calcified lesions, because the Committee on BI-RADS® concludes that the association of subjectively estimated breast density with changes in the sensitivity of mammography is clinically more important than the relatively smaller effect of percentage breast density as an indicator for breast cancer risk.

The Committee on BI-RADS® indeed is aware of recent and continuing investigations of percent-age breast density as an indicator for breast cancer risk, and by eliminating percentage ranges they do not intend to compromise or impede any such research. They simply recognize the reality that interpreting physicians will continue to use density categories in mammography reports as they have done over the past years, independent of BI-RADS® guidance on percentage breast density. They further recognize that both subjective estimates and planimetry measurements of breast density based on area as depicted on (2-D) mammograms are imprecise indicators of the volume of dense tissue, which may be measured using (3-D) cross-sectional breast imaging modalities. They await publication of robust volume-based breast density data, using validated percentage cut points (not necessarily

quartiles) that are readily and reproducibly determined at imaging, before again indicating percentage ranges for BI-RADS® density categories. They also urge avoidance of numbers to classify breast density instead of BI-RADS® terminology in order to avoid confusion with BI-RADS® assessment categories, which are numbered. Some breasts may appear more or less dense when imaged using full-field digital mammography compared to screen-film mammography. Superior depiction of the skin line by digital mammography provides the observer with a more accurate (and usually larger) estimate of the extent of the subcutaneous fat. However, no change in the distribution across density categories has been observed when comparing full-field digital mammography with screen-film mammography.

Screening mammography is used to detect unexpected breast cancer in asymptomatic women, supplementing history taking and physical examination. Standard mammographic views include craniocaudal (CC) and mediolateral oblique (MLO) views. The MLO view images the greatest volume of breast tissue, including the upper outer quadrant and the axillary tail of Spence. Compared with the MLO view, the CC view provides better visualization of the medial aspect of the breast and permits greater breast compression. The 90-degree lateral view is used along with the CC view to triangulate the exact location of an abnormality. Spot compression may be done in any projection by using a small compression device, which is placed directly over a mammographic abnormality that is obscured by overlying tissues. The compression device minimizes motion artifact, improves definition, separates overlying tissues, and decreases the radiation dose needed to penetrate the breast. Magnification techniques ($\times 1.5$) often are combined with spot compression to better resolve calcifications and the margins of masses [12-18].

The most important findings on mammography (that are either of concern at screening, inherently suspicious, new, or seen to be larger or more extensive when compared to previous examination) are:

- a. Mass: size, morphology (shape, margin), density, associated calcifications, associated features, location.
- b. Calcifications: morphology, description of typically benign type or description of the shape of particles, distribution (may not be appropriate for typically benign calcifications), associated features, location.
- c. Architectural distortion: associated calcifications, associated features, location.
- d. Asymmetries (asymmetry, global asymmetry, focal asymmetry, developing asymmetry): associated calcifications, associated features, location.
- e. Intramammary lymph node (rarely important): location.
- f. Skin lesion: location.
- g. Solitary dilated duct (rarely present): location.

Comparison to previous examination may assume importance if the finding of concern requires an evaluation of change or stability. Comparison is not important when a finding has unequivocally benign features. Comparison may be irrelevant when the finding is inherently suspicious for malignancy.

All final assessments (BI-RADS® categories 1, 2, 3, 4, 5, and 6 should be based on thorough evaluation of the mammographic features of concern or after determination that an examination is negative or benign.

An incomplete (category 0) assessment is usually given for screening examinations when additional imaging evaluation is recommended before it is appropriate to render a final assessment. There may be rare situations in the screening setting in which a category 4 or 5 assessment is used, but this practice is discouraged because it may compromise some aspects of outcome analysis. A recall (category 0) assessment should include specific suggestions for the next course of action (spot-compression magnification views, US, etc.)

In most circumstances and when feasible, if a mammography examination is not assessed as negative or benign, the current examination should be compared with prior examination(s). The interpreting physician should use judgment on how vigorously to attempt obtaining prior examinations, given the likelihood of success of such an endeavor and the likelihood that comparison will affect the final assessment. In this context, it is important to note that comparison with previous examination(s) may be irrelevant when a finding is inherently suspicious for malignancy.

Category 0 should be used for prior image comparison only when such comparison is required to make a final assessment. When category 0 is used in the context of awaiting prior examinations for comparison, there should be in place a tracking procedure guaranteeing with 100% reliability that a final assessment will be made within 30 days (preferably sooner) even if prior examinations do not become available. Some mammography practices may reasonably choose never to use category 0 in the context of awaiting prior examinations simply because they do not have a 100% reliable tracking procedure. If a mammography examination is assessed as category 0 in the context of awaiting prior examinations and then the prior examinations do become available, an addendum to the initial mammography report should be issued, including a revised assessment.

Category 1: Negative. This is a normal examination.

Category 2: Benign. Like category 1, this is a normal assessment, but here the interpreter chooses to describe a benign finding in the mammography report. Involuting calcified fibroadenomas, skin calcifications, metallic foreign bodies (such as core biopsy and surgical clips), and fat-containing lesions (such as oil cysts, lipomas, galactoceles, and mixed-density hamartomas) all have characteristically benign appearances and may be described with confidence. The interpreter may also choose to describe intramammary lymph nodes, vascular calcification, implants, or architectural distortion clearly related to prior surgery while still concluding that there is no mammographic evidence of malignancy. On the other hand, the interpreter may choose not to describe such findings, in which case the examination should be assessed as negative (category 1). Note that both category 1 and category 2 assessments indicate that there is no mammographic evidence of malignancy. Both should be followed by the management recommendation for routine mammography screening. The difference is that category 2 should be used when describing one or more specific benign mammographic findings in the report, whereas category 1 should be used when no such findings are described (even if such findings are present).

Category 3: Probably Benign. A finding assessed using this category should have a $\leq 2\%$ likelihood of malignancy, but greater than the essentially 0% likelihood of malignancy of a characteristically benign finding. A probably benign finding is not expected to change over the suggested period of imaging surveillance, but the interpreting physician prefers to establish stability of the finding before recommending management limited to routine mammography screening.

There are several prospective clinical studies demonstrating the safety and efficacy of periodic mammographic surveillance instead of biopsy for specific mammographic findings. Three specific findings are validated as being probably benign (non-calcified circumscribed solid mass, focal asymmetry, and solitary group of punctate calcifications). All the previously cited studies emphasize the need to conduct a complete diagnostic imaging evaluation before making a probably benign (category 3) assessment; hence, it is recommended not to render such an assessment in interpreting a screening mammography examination. The practice of rendering category 3 assessments directly from screening examination also has been shown to result in adverse outcomes: 1) unnecessary follow-up of many lesions that could have been promptly assessed as benign, and 2) delayed diagnosis of a small number of cancers that otherwise may have been smaller in size and less likely to be advanced in stage. Also, all the previously cited studies exclude palpable lesions, so the use of a probably benign assessment for a palpable lesion is not supported by robust scientific data, although there are two single-institution studies that do report successful outcomes for palpable lesions.

Finally, because evidence from previously cited studies indicates the need for biopsy rather than continued surveillance when a probably benign finding increases in size or extent, it is not prudent to render a category 3 assessment when a finding that otherwise meets “probably benign” imaging criteria is either new or has increased in size or extent.

Category 4: Suspicious. This category is reserved for findings that do not have the classic appearance of malignancy but are sufficiently suspicious to justify a recommendation for biopsy. The ceiling for category 3 assessment is a 2% likelihood of malignancy and the floor for category 5 assessment is 95%, so category 4 assessments cover the wide range of likelihood of malignancy in between. Thus, almost all recommendations for breast interventional procedures will come from assessments made using this category.

Category 5: Highly Suggestive of Malignancy. These assessments carry a very high probability ($\geq 95\%$) of malignancy. This category initially was established to involve lesions for which 1-stage surgical treatment was considered without preliminary biopsy, in an era when preoperative wire localization was the primary breast interventional procedure. Nowadays, given the widespread acceptance of imaging-guided percutaneous biopsy, 1-stage surgery is rarely, if ever, performed. Rather, current oncologic management almost always involves tissue diagnosis of malignancy via percutaneous tissue sampling to facilitate treatment options, such as when sentinel node biopsy is included in surgical management or when neoadjuvant chemotherapy is administered prior to surgery. Therefore, the current rationale for using a category 5 assessment is to identify lesions for which any non-malignant percutaneous tissue diagnosis is automatically considered discordant, resulting in the recommendation for repeat (usually surgical) biopsy.

Category 6: Known Biopsy-Proven Malignancy. This category is reserved for examinations performed after biopsy proof of malignancy (imaging performed after percutaneous biopsy but prior to complete surgical excision), in which there are no mammographic abnormalities other than the known cancer that might need additional evaluation.

Digital mammography was developed to allow the observer to manipulate the degree of contrast in the image. Digital mammography captures x-ray information after it passes through the breast in a digital format—without a film—that can be viewed, edited, and transferred electronically to viewing stations and picture archiving and communications systems viewers. This is especially useful in women with dense breasts and women less than

50 years of age. The use of digital breast tomosynthesis with 3D images has been introduced as an alternative to standard 2D mammography imaging that is limited by superimposition of breast parenchyma and breast density. The STORM trial reported that in 7,292 women screened, 3D mammography had a higher cancer detection rate and fewer false-positive recalls than the standard 2D imaging [19].

Specific mammographic features that suggest a diagnosis of breast cancer include a solid mass with or without stellate features, asymmetric thickening of breast tissues or architectural distortion, and clustered microcalcifications. The presence of fine, stippled calcium in and around a suspicious lesion is suggestive of breast cancer and occurs in as many as 50% of nonpalpable cancers. These microcalcifications are an especially important sign of cancer in younger women, in whom it may be the only mammographic abnormality.

Figure 17. Microcalcifications in mammography.

The usual approach to the evaluation of a well-defined mass on mammography includes an assessment of the shape, size, margins, density, orientation, presence of a fatty halo, and presence of other findings (i.e., calcifications, Figure 17). Benign lesions tend to be isodense or less dense than the parenchyma and to have very circumscribed margins, whereas malignant masses are more often of greater density and have fine irregularity or micronodularity on their borders (Figure 18). A microlobulated margin appears as fine nodularity or undulation of the edge of the lesion and implies a more malignant nature.

The shapes of masses that are circumscribed may be oval, round, or lobular. The margination that is described as circumscribed allows one to visualize a fine, clear edge around the entire mass (i.e., cyst, Figure 19). Often masses that are circumscribed may be overlapped by parenchyma in some areas. These are described as obscured or partially circumscribed.

A basic division of well-circumscribed masses based on their density is of help in determining possible etiologies of and approach to such lesions. Masses that are fatty such as lipomas, oil cysts, and galactoceles and circumscribed masses that are mixed density are characteristically benign. Isodense circumscribed masses include benign and malignant lesions, and an evaluation of the borders is critical to help differentiate these etiologies. Masses that are of high density, particularly for their size, are of concern for malignancies. However, in a study of radiologists' interpretations of mass density, Jackson et al., [20] found

that the assessment of mammographic density of masses was quite variable among different readers; in addition, the density assessment was of limited value in the prediction of benign versus malignant for noncalcified breast masses.

Figure 18. Fibroadenomas in mammography (arrows).

Figure 19. Breast cyst in mammography.

The mammographic feature of greatest importance in assessing a relatively circumscribed isodense mass is its margination. Any waviness, notching, or indistinctness of the margins of a mass should be regarded with suspicion. The presence of a halo sign, i.e., a fine radiolucent ring surrounding a well-defined mass, has long been considered to be a mammographic sign of benignancy. The halo may be due to compression of fat by the mass or to Mach effect. Swann et al. [21] have, however, described 25 malignant lesions from approximately 1,000 breast cancers in which a halo sign was present. The presence of a halo suggests but does not guarantee a benign process. Certainly, the presence of a partially circumscribed margin and a partially indistinct margin is suspicious, and biopsy is indicated in this situation.

Stability in size from prior mammography is an important factor that suggests that a circumscribed non-cystic mass is benign. The growth rates of breast cancers are quite variable. In two series, the mean doubling times for mammary carcinoma have been found to be 212 and 325 days, respectively [22, 23]. The lack of interval change suggests that a well-defined lesion is more likely benign, but this is not confirmatory. Meyer and Kopans [24] reported five cases of occult cancers that did not change in size on follow-up mammography over a minimum of 2 years and a maximum of 4.5 years from the original study. Therefore, if a nodule is followed and there is no interval change in the size at 6 months or 1 year, continued follow-up is necessary. In addition, the other features of density and margination are used to decide whether to follow or biopsy a circumscribed mass.

Small solid breast lesions that are radiologically indeterminate sometimes yield an indeterminate histopathological assessment following a radiologically guided biopsy.

Although some centers may wish to just follow these lesions up, increasingly these are being treated using radiological wire localization followed by open surgery in the form of a wide local excision (Figure 20, 21, 22). However many of these are subsequently benign on final surgical pathology.

Figure 20. Radiological wire localization of breast lesion.

Figure 21. Radiological wire localization followed by open surgery in the form of a wide local excision.

Figure 22. Specimen of open biopsy after Kopans wire used in needle localization.

Figure 23. Important step is that of marking the specimen with two sutures (long suture for lateral, and short suture for superior).

Important step is the marking of the specimen with two sutures in order to assist the pathologist for better orientation on specimen findings (Figure 23). More recently there has been alternative radiological management to excise biopsy proven benign lesions, usually fibroadenomas, in women wishing to have them removed. This has been with vacuum assisted biopsy devices, such as the mammotome™ (Johnson and Johnson Ethicon Endo-Surgery Inc, Cincinnati, Ohio, USA), Encor™ (C.R. Bard, New York, USA) and Suros ATEC™ (Suros Surgical Systems Inc, Indianapolis, USA). The advantages of these minimally invasive approaches to many women made this technique increasingly popular. They can be performed usually in less than 30 min, with only local anaesthetic and a minimal scar. Complication rates are very low, and the procedures are extremely well tolerated. These procedures are particularly suitable for young women where risk of the lesion being non benign is very low, and cosmesis is premium. The obvious limitation of this technique however, is that as it is only able to remove lesions in a “piecemeal” fashion. Such excisions are unable to provide an assessment of margins of the excision, thus there is no way of determining completeness of excision and whether any residual lesion is left behind. While this may not be particularly relevant if the lesions excised are fibroadenomas, or other such similar benign lesions, it will however obviate the vacuum assisted excision from being utilised for many other more “border-line” lesions where completeness of excision and a full margin status is desirable or essential [1, 4, 12].

Since 2001 the breast lesion excision system (BLES, Intact Medical, Framingham, USA), has been used as an alternative large biopsy device to other vacuum assisted biopsy devices in over 50,000 cases in the USA. It has been well validated as a safe and efficacious biopsy procedure. It however has the unique feature of using radiofrequency cautery to excise a small but whole sample in one piece with intact architecture and clear margins, as a swift local anaesthetic outpatient procedure.²⁵

The BLES biopsy is an efficacious technique at excising small indeterminate breast lesions with a complete margin without the need for follow-up diagnostic surgery in the majority (Figures 24, 25, 26).

In cases with post biopsy parenchymal hemorrhage, a localized area of increased density corresponding to increased fluid and blood may be seen. Needle tracts may be noted as subtle, cylindrical mammographic densities in a projection parallel to the biopsy tract with 11-gauge needles. Fourteen gauge needles have not been shown to produce any detectable abnormality. Following vacuum-assisted core biopsy, gas pockets and hematomas are common, but they resolve within 2 to 4 weeks. [28] Overall, post-core biopsy changes should not be recognized on mammography after approximately 6 months; any density after this period likely represents an abnormality and should be further evaluated [29].

Figure 24. Breast lesion excision system.

Figure 25. Removing suspicious breast area using BLES.

Post-core biopsy mammographic changes are few and very uncommon. In cases of clip placement, a small metallic clip should be visible at the biopsy site (Figure 27). Clips may demonstrate some migration from the area of initial placement [1, 26, 27].

Figure 26. Post excision trauma after BLES.

Figure 27. Clip placement after biopsy.

Post-excisional breast biopsies, which involve the removal of a larger amount of breast tissue, demonstrate significantly more imaging findings. Fifty percent of benign excisional breast biopsies show some mammographic change [30].

Postsurgical mammograms are ideally performed at about 3 to 6 months after surgery and serve as new baseline views. Benign pathologies, however, may not prompt postsurgical imaging unless there is a need to confirm successful removal of a lesion or evaluate for postoperative complications.

In a postsurgical mammogram, a thin metallic marker is placed on the surgical skin scar to indicate its location on the images. The most commonly viewed post excisional change is architectural parenchymal distortion, followed by overlying focal skin thickening. These changes are seen mostly in the first 6 months after surgery. Other findings include calcifications or fat necrosis. Occasionally, 6 or more months after the procedure, calcifications form in the post excisional bed. Most are dystrophic in nature or associated with fat necrosis or oil cysts. Small irregular calcifications mimicking malignancy may also be seen and should be closely monitored for malignancy [31].

Ductography

Breast ductography (also known as galactography) is an imaging technique which is used to evaluate lesions causing nipple discharge. It helps in precisely locating the mass within breast tissue and gives useful information for surgical approach and planning.

Figure 28. Ductography.

Figure 29. Intraductal papillomas are seen as small filling defects surrounded by contrast media.

The primary indication for ductography is nipple discharge, particularly when the fluid contains blood. Radiopaque contrast media is injected into one or more of the major ducts and mammography is performed (Figure 28). A duct is gently enlarged with a dilator and then a small, blunt cannula (sialogram needle of 30 gauge) is inserted under sterile conditions into the nipple ampulla. With the patient in a supine position, 0.1 to 0.2 mL of dilute contrast media is injected and a standard two view mammography (CC and MLO projections) are obtained without compression. Intraductal papillomas are seen as small filling defects surrounded by contrast media (Figure 29). Cancers may appear as irregular masses or as multiple intraluminal filling defects (Figure 30) [4, 12].

Figure 30. Cancers may appear as irregular masses or as multiple intraluminal filling defects.

The majority of the lesions found in ducts are duct papillomas. Current practice holds that these lesions should be excised to exclude a malignant lesion. If the duct lesion is large enough, ultrasound guided percutaneous biopsy can make the diagnosis of a papilloma quite successfully. The duct is excised after it is filled carefully with dye.

3. MAGNETIC RESONANCE IMAGING (MRI)

In the process of evaluating magnetic resonance imaging (MRI) as a means of characterizing mammographic abnormalities, additional breast lesions have been detected. However, in the circumstance of negative findings on both mammography and physical examination, the probability of a breast cancer being diagnosed by MRI is extremely low. Contrast enhanced breast MRI indications include (a) evaluation of the extension of known breast cancer, (b) detection of contralateral breast cancer in women with newly diagnosed breast cancer, (c) screening for women who are at high risk and/or positive for BRCA1 and BRCA2, (d) assessment of neoadjuvant chemotherapy response, (e) evaluation of chest wall invasion or mastectomy site for recurrence, and (f) detection of breast cancer in women with axillary metastases and a normal mammogram [1, 32, 33, 34].

The patient receives an intravenous line and is given gadolinium for contrast enhancement. Then 20 minutes of motionless scan time follows. [35] There are three different patterns of dynamic enhancement. The type 1 pattern (persistent) shows slow, progressive contrast uptake over time and is suggestive of benignity. The type II contrast pattern (plateau) shows a rapid uptake in contrast and then a leveling off of uptake. This pattern is suggestive of malignancy. The type III pattern (washout) is indicative of malignancy. [36] The diagnostic evaluation must also include the assessment of lesion morphology, which requires high-resolution imaging. The border of the lesion is the most important feature. Spiculated and irregular margins have a positive predictive value of malignancy ranging from 76% to

91%. Most benign masses have a smooth border with a negative predictive value for malignancy of 90%. [36, 37] DCIS is suggested by small, clumped foci that are within a segment or duct [38].

The use of dedicated breast coils is mandatory in the MRI imaging of the breast. A BIRADS lexicon is assigned to each examination and an abnormality noted on MRI that is not seen on mammography requires a focused ultrasound examination for further assessment. If the abnormality is not seen on corresponding mammogram or ultrasound then MRI guided biopsy is necessary. Some clinical scenarios where MRI may be useful include the evaluation of a patient who presents with nodal metastasis from breast cancer without an identifiable primary tumor; to assess response to therapy in the setting of neoadjuvant systemic treatment; to select patients for partial breast irradiation techniques; and evaluation of the treated breast for tumor recurrence.

There is current interest in the use of MRI to screen breasts of high-risk women and of women with a newly diagnosed breast cancer. In the first case, women who have a strong family history of breast cancer or who carry known genetic mutations require screening at an early age, because mammographic evaluation is limited due to the increased breast density in younger women [4].

In the second case, an MRI study of the contralateral breast in women with a known breast cancer has shown a contralateral breast cancer in 5.7% of these women. MRI can also detect additional tumors in the index breast (multifocal or multicentric disease) that may be missed on routine breast imaging and this may alter surgical decision making. In fact, MRI has been advocated by some for routine use in surgical treatment planning based on the fact that additional disease can be identified with this advanced imaging modality and the extent of disease may be more accurately assessed [4].

Preoperative imaging can change the case management approach in a significant number of cases: 18% using US and 11% to 30% using MRI. [8, 39, 40] US and MRI are generally more sensitive than mammography for invasive carcinomas, especially in dense and heterogeneous breasts. MRI is commonly used for the detection of multicentric and multifocal diseases once cancer is diagnosed [1].

A randomized trial performed in the United Kingdom (COMICE trial)⁴¹ which enrolled 1,623 women did not show a decrease in rates of reoperation in those women randomized to undergo MRI in addition to mammography and ultrasonography (19%) compared to those undergoing standard breast imaging without MRI (19%). Houssami et al., [42] performed a meta-analysis including 2 randomized trials and 7 comparative cohort studies to examine the effect of preoperative MRI compared to standard preoperative evaluation on surgical outcomes. They reported that the use of MRI was associated with increased mastectomy rates. This is problematic since there is no evidence that the additional disease detected by MRI is of clinical or biologic significance, particularly in light of the low local-regional failure rates currently reported in patients undergoing breast conserving surgery who receive whole breast irradiation and systemic therapies [4, 42].

The manifestation of an isolated metastatic axillary lymph node without any clinical and radiologic evidence of primary breast cancer is uncommon, but this disease most commonly originates from breast cancer in women. For these cases, the traditional therapy has been upper outer quadrantectomy or blind mastectomy with axillary lymph node dissection, with or without radiation. However, 30 to 40% of the upper outer quadrantectomy or blind mastectomy specimens show no histologic evidence of carcinoma, and the survival rate of

patients who undergo blind mastectomy with axillary dissection is similar to those who undergo axillary dissection only [43]. Breast MRI techniques have improved significantly in recent years, and MRI with dynamic enhancement has been established as an important imaging modality for evaluating breast cancer with the highest sensitivity.

A Korean study [44] investigated the ability of breast MR imaging to identify the primary malignant focuses in patients with metastatic axillary lymph nodes and initially negative mammography and sonography, and correlated the results with the conventional imaging. The authors concluded that the high sensitivity of contrast-enhanced breast MRI played an essential role in evaluating occult breast cancer in patients who presented with a metastatic axillary lymph node with an unknown primary malignancy, and contrast-enhanced breast MRI also played an essential role for determining the therapeutic plan. In 90% of their cases, histologic work-up for the lesions detected on the breast MRI was practically feasible with successful localization being achieved under MR-guided, second-look US, or MR-correlated mammography.

With its recent technical advances, contrast-enhanced MRI plays an important role in identifying primary breast cancer, for defining the extent of tumor and for helping decide the therapeutic plans. While mammography is the primary imaging modality used to evaluate breast lesions, the false negative rate for mammography has been reported to be about 30%. [45, 46] The sensitivity of mammography is especially limited when the lesion is within dense breast parenchyma, and it is often as low as 45%. [8] Among mammography, US and MRI, MRI is the most sensitive method for evaluating breast cancer and it is well recognized that MRI can detect otherwise occult breast cancer [8, 32, 47].

A few previous reports that detailed the MR images of patients with axillary lymph node metastases, and the patients had prior negative clinical and mammography findings, demonstrated 36%, 75% and 86% rates of detecting cancer by breast MRI, respectively. [48, 49] In another previous study [50] on patients with axillary lymph node metastasis and negative clinical, mammographic and US findings, the investigators showed a lesion detection rate of 64% with breast MRI, and 67% of the detected lesions were found to be primary breast cancer [50].

Figure 31. Small breast cancer in MRI.

Figure 32. MRI Right breast tumor.

The reported mean size of the lesions visible by breast MRI alone was between 4.8 to 14.6 mm (Figure 31, 32) [44, 51].

Historically, the reported incidence of axillary metastasis in patients with DCIS is 1-2%, but the prevalence of positive lymph nodes in patients with pure DCIS is approximately 2-13% with performing immunohistochemical staining [52, 53].

Many authors suggest that before developing a therapeutic plan, breast MRI must be performed for those patients with axillary lymph node metastasis and who are without evidence of primary breast cancer. Although contrast-enhanced MRI has the highest sensitivity among the many imaging modalities for the breast, the specificity of breast MRI is low. [8, 47, 53] Therefore, preoperative biopsy or localization of the MRI-detected lesion is necessary. [54] Yet MR imaging-guided biopsy or localization requires commercially available MRI guiding equipment. Also, the cost-effectiveness of MRI-guided biopsy or localization has not yet been fully assessed. [55] Even when MRI guiding equipment is available, lesions in the medial breast are difficult to access and small enhancing lesions (around 5 mm) may be difficult to localize due to the transient nature of contrast enhancement and the obscuring that occurs when placing the biopsy needle. MR imaging-guided biopsy or localization is also a time-consuming procedure that lasts as long as 45 to 60 minutes [51, 54, 55].

A few studies have reported excellent performance of MR-guided second-look US localization. [48, 56] Therefore, localization with using MR-correlated mammography or MR-guided second-look US can be a cheaper, practical imaging alternative.

When BI-RADS category 2 or 3 lesions are detected on conventional images, but they do not correlate with the MR findings of the patients with suspicious occult breast cancer, then we should not neglect these lesions.

However, biopsy for all benign-looking lesions is not desirable or even necessarily meaningful [57]. When there is a benign or benign-looking lesion on the conventional images of the patients with metastatic axillary lymph node(s) and an unknown primary malignancy, then the conventional images should first be correlated with MR findings before performing a biopsy of the lesions [44].

3.1. MRI Report Organization

According to ACR BI-RADS® atlas the MRI reporting system should be concise and organized. Any pertinent clinical history that may affect scan interpretation, as well as any MRI acquisition techniques (including post-processing information) that may affect the scan interpretation, should be described (Table 5). The breast MRI report should first describe the amount of fibroglandular tissue and the background parenchymal enhancement (BPE -Table 6).

Abnormal enhancement (unique and separate from the BPE) is described based on morphology, distribution, and kinetics. Results from any physiologic or parametric imaging should be described.

An assessment is rendered that includes the degree of concern and any recommendation(s). Benign findings need not be reported, especially if the interpreting physician is concerned that the referring clinician or patient might infer anything other than absolute confidence in benignity.

Table 5. Report organization

	Report Structure
1.	Indication for examination
2.	MRI technique
3.	Succinct description of overall breast composition
4.	Clear description of any important findings
5.	Comparison to previous examination(s)
6.	Assessment
7.	Management

Table 6. Breast tissue: Background Parenchymal Enhancement (BPE)

	Background Parenchymal Enhancement
a.	Minimal
b.	Mild
c.	Moderate
d.	Marked

3.1.1. Indication for Examination

Provide a brief description of the indication for examination. For example, this may be high-risk screening, follow-up of a probably benign lesion, follow-up of cancer treated with neoadjuvant chemotherapy, or evaluation of the newly diagnosed cancer patient.

As background parenchymal enhancement can be affected by cyclical hormonal changes, it may be helpful to include menstrual history. If the patient is pre-menopausal, the week of the menstrual cycle may be important information to aid in interpretation. Current therapy (neoadjuvant, adjuvant, hormonal, or radiation therapy) for breast cancer treatment in the pre- or postsurgical setting may be important information and may inform exam interpretation.

The indication for examination should contain a concise description of the patient’s clinical history, including:

- a. Reason for performing the exam (e.g., screening, staging, problem solving)
- b. Clinical abnormalities, including size, location, and duration
 - i. Palpable finding
 - ii. Nipple discharge
 - iii. Other pertinent clinical findings or history
- c. Previous biopsies
 - i. Biopsy type
 - ii. Biopsy location
 - iii. Benign or malignant pathology (cytology or histology)
- d. Hormonal status if applicable
 - i. Pre- or post-menopausal
 - ii. Menstrual cycle phase (second week or other) or last menstrual period
 - iii. Peripartum
 - iv. Exogenous hormone therapy, tamoxifen, aromatase inhibitors, or other hormones or medications/herbs/vitamins that might influence MRI

3.1.2. MRI Technique

A detailed description of the technical factors of how the MRI examination was obtained must be given. At a minimum, a bright-fluid sequence of both breasts should be obtained. Pre- and post-gadolinium T1-weighted images should be obtained, preferably with fat suppression, simultaneously of both breasts. Subtraction imaging may be desired as well as other as processing techniques and parametric analysis. Elements of this description routinely include:

- a. Right, left, or both breasts
- b. Location of markers and their significance (scar, nipple, palpable lesion, etc.)
- c. Weighting
 - i. T1 weighted
 - ii. T2 weighted
 - iii. Fat saturation
 - iv. Scan orientation and plane
 - v. Other pertinent pulse sequence features
- d. Contrast dose
 - i. Name of contrast agent
 - ii. Dosage (mmol/kg) and volume (in cc)
 - iii. Injection type: bolus or infusion
 - iv. Timing (relationship of bolus injection to scan start time and scan length)
 - v. If multiple scans: number of post-contrast scans and acquisition techniques of each (how fast, how many slices, and slice thickness)
- e. Post-processing techniques as applicable
 - i. MPR/MIP (Multiplanar reconstruction / Maximum Intensity Projection)
 - ii. Time/signal intensity curves
 - iii. Subtraction
 - iv. Other techniques

3.1.3. Succinct Description of Overall Breast Composition

This should include an overall description of the breast composition, including:

- a. The amount of FGT (FibroGlandular breast Tissue) that is present

The four categories of breast composition are defined by the visually estimated content of FGT within the breasts. If the breasts are not of apparently equal amounts of FGT the breast with the most FGT should be used to categorize breast composition. Although there may be considerable variation in visually estimating breast composition, categorizing based on percentages (and specifically into quartiles) is not recommended.

The BIRADS® committee recognizes that quantification of breast FGT volume on MRI may be feasible in the future, but they await publication of robust data before endorsing percentage recommendations. They urge the use of BI-RADS® terminology instead of numbers to classify breast FGT in order to eliminate any possible confusion with the BIRADS® assessment categories, which are numbered.

- b. The amount of background parenchymal enhancement in the image

Figure 33. Breast MRI: Lesion over implant.

The four categories of BPE are defined by the visually estimated enhancement of the FGT of the breast(s). If the breasts are not of an apparently equal amount of BPE, the breast with the most BPE should be used to categorize BPE. In the event that treatment has altered BPE in one or both breasts, this can be reported. Although there may be considerable variation in visually estimating BPE, categorizing based on percentages (and specifically into quartiles) is not recommended.

Quantification of BPE volume and intensity on MRI may be feasible in the future, but the BIRADS® committee awaits publication of robust data on that topic before endorsing percentage recommendations.

The committee recognizes that there are variations in BPE distribution and morphology. However, committee defers on recommending descriptions of distribution or morphology until additional data are available. Currently, BPE refers to the volume of enhancement and the intensity of enhancement. On bilateral scans, describe whether the pattern is asymmetric or symmetric, if appropriate. Asymmetric denotes more enhancement in one breast than in the other. Symmetric enhancement is mirror image.

c. Whether implants are present (Figure 33)

If an implant is present, it should be so stated in the report. Information should include its composition (saline, silicone, or other) and the number of lumens (single or multiple).

3.1.4. Clear Description of Any Important Findings

Abnormal enhancement is unique and separate from BPE. Its description should indicate the breast in which the abnormal enhancement occurs, the lesion type, and modifiers. The clinical location of the abnormality as extrapolated from the MRI location (based on clock-face position and quadrant location) should be reported. It should be recognized that there may be variation in location of a clinically detected lesion (patient is upright or supine), a mammographically detected lesion (patient is upright and compressed), a sonographically detected lesion (patient is supine or supine oblique), and an MRI-detected lesion (patient is prone) based on positional differences.

A more consistent measurement is the distance from the nipple. It is encouraged that distance from the nipple for a lesion is reported in order to facilitate correlation between modalities, although it should be understood that one should expect some difference in distance from the nipple among the breast imaging modalities. For bilateral axial examinations, the breasts should be pointing up, following the cross-sectional imaging convention.

The descriptors should include techniques, all data, and any findings from MRI listed in Table 7.

Also, it is recognized that other techniques may be used in the evaluation of breast lesions. Newer and evolving techniques are constantly being introduced. Findings from other techniques, such as diffusion-weighted imaging or MR spectroscopy, should be reported if clinically important.

3.1.5. Comparison to Previous Examination(s)

Include a statement indicating that the current examination has been compared to previous examination(s) with specific date(s). If this is not included, it should be assumed that no comparison has been made; however, it is preferable to indicate explicitly that no comparison was made. Comparison to a previous examination may assume importance if the finding of concern requires an evaluation of change or stability. Comparison is less important when the finding has characteristically benign features. Comparison may be irrelevant if the finding is inherently suspicious for malignancy. Information in this area should include:

- a. Previous MRI with the date of examination
- b. Other imaging studies (mammogram, US, nuclear medicine examination, other) and date of examination (Figure 34, 35, 36).

Table 7. Description of all data and any important findings

- a. Size
- b. Location
 - i. Right or left
 - ii. Breast quadrant and clock-face position (or central, retroareolar, and axillary tail descriptors)
 - iii. Distance from nipple, skin, or chest wall in centimeters (if applicable)
- Descriptors for abnormal enhancement:
- c. Findings associated with abnormal enhancement include:
 - i. Artifacts that affect interpretation
 - ii. Focus: a tiny dot of enhancement that does not clearly represent a space-occupying lesion or mass and does not clearly show a mass on precontrast imaging
 - iii. Masses: space-occupying lesions, usually spherical or ball-like, may displace or retract surrounding breast tissue
- Descriptors - modifiers describing a mass:
 - (a) Shape: describes the overall morphology of the enhancement
 - ☐ Oval (includes lobulated)
 - ☐ Round
 - ☐ Irregular
 - (b) Margin: describes the borders
 - ☐ Circumscribed
 - ☐ Not circumscribed
 - Irregular
 - Spiculated
 - (c) Internal enhancement characteristics
 - Homogeneous
 - Heterogeneous
 - Rim enhancement
 - Dark internal septations
- iv. Non-mass enhancement (NME): modifiers describing enhancement patterns with a specific MRI pattern
 - (a) Distribution
 - Focal
 - Linear
 - Segmental
 - Regional
 - Multiple regions
 - Diffuse
 - (b) Internal enhancement patterns (for all other types)
 - Homogeneous
 - Heterogeneous
 - Clumped
 - Clustered ring
- v. Intramammary lymph node (rarely important)
- vi. Skin lesion
- vii. Non-enhancing findings
 - a. Ductal precontrast high signal on T1W
 - b. Cyst
 - c. Postoperative collections (hematoma/seroma)
 - d. Post-therapy skin thickening and trabecular thickening
 - e. Non-enhancing mass
 - f. Architectural distortion
 - g. Signal void from foreign bodies, clips, etc.
- viii. Associated features
 - a. Nipple retraction
 - b. Nipple invasion
 - c. Skin retraction
 - d. Skin thickening
 - e. Skin invasion (Direct invasion, Inflammatory cancer)
 - f. Axillary adenopathy
 - g. Pectoralis muscle invasion
 - h. Chest wall invasion
 - i. Architectural distortion
- ix. Fat-containing lesions
 - (a) Lymph nodes
 - a. Normal
 - b. Abnormal
 - (b) Fat necrosis
 - (c) Hamartoma
 - (d) Postoperative seroma/hematoma with fat
- x. Stability: describe how enhancement changed (if new, stable, or changed in size from previous examination)
- xi. Kinetic curve assessment
 - (a) The fastest enhancing portion of the lesion or the most suspicious washout curve pattern in the lesion should be assessed
 - Sample fast enhancing areas

Table 7. (Continued)

- Sample for and report on the worst looking curve shape
- (b) Signal intensity/time curve
 - Initial enhancement phase-describes the enhancement pattern within the first 2 minutes or when the curve starts to change
 - Slow
 - Medium
 - Fast
 - Delayed phase – describe the enhancement pattern after 2 minutes or after the curve starts to change
 - Persistent
 - Plateau
 - Washout
- xii. Implants
 - (a) Implant material and lumen type
 - Saline
 - Silicone
 - Intact
 - Ruptured
 - Other implant material (such as soy oil, polypropylene, polyurethane, and sponges; includes direct injections)
 - Lumen type
 - (b) Implant location
 - Rectoglandular
 - Retropectoral
 - (c) Abnormal implant contour
 - Focal bulge
 - (d) Intracapsular silicone findings
 - Radial folds
 - Subcapsular line
 - Keyhole design (teardrop, noose)
 - Linguine sign
 - (e) Extracapsular silicone
 - Breast
 - Lymph nodes
 - (f) Water droplets
 - (g) Peri-impland fluid

3.1.6. Assessment

This is a description of an overall summary of MRI findings, including assessment.

Incorporating an assessment category in the overall summary of the breast MRI report is sound medical practice. All final impressions should be complete with each lesion fully categorized.

Figure 34. Mammography findings in a patient with cancer and large cysts in right breast.

Figure 35. MRI of the same patient with breast cancer and cysts.

Figure 36. Abnormal enhancement on MRI.

An incomplete assessment (category 0) is used when full diagnostic imaging has not been performed and should be given only when additional imaging or clinical evaluation is recommended to establish the benignity of a finding (e.g., a possible intramammary lymph node or fat necrosis at MRI may require additional mammography and/or US examination).

3.1.7. Management

This is a description of patient management recommendations, as appropriate. If an incomplete assessment (category 0) is rendered, a specific suggestion for the next course of action should be given (physical examination, diagnostic mammography, targeted diagnostic US, etc.). Note that an incomplete assessment (category 0) should not be rendered when recommending targeted US in order to determine the feasibility of performing biopsy using sonographic guidance; such a scenario requires the use of a category 4 or 5 assessment (suspicious or highly suggestive of malignancy).

If a suspicious abnormality is detected, the report should indicate that a biopsy should be performed in the absence of clinical contraindication. This means that the radiologist has sufficient concern that a biopsy is warranted; the term “clinical contraindication” indicates that there may be reasons why the patient and her physician might wish to defer the biopsy.

Concordance between BIRADS® assessment categories and management recommendations is listed in Table 8.

MRI of the breast has evolved into an important tool in breast imaging with increasing indications for its use. MRI has plenty advantages such as increased contrast of tissues, multiple views, less ionizing radiation, use of contrast enhancement time course to differentiate benign from malignant lesions, detecting lesions close to chest wall and occult breast lesions, higher sensitivity but still poor specificity. The high sensitivity of MRI but it's not so high specificity creates many false-positive results and callbacks for further evaluation, including second-look ultrasound studies and biopsies. Another disadvantage is the newly recognized but rare side effect of MRI, nephrogenic sclerosing fibrosis that is related to intravenous administration of MRI contrast agents. Special attention is needed for women with impaired renal function or renal failure. [58] The limitations of MRI include its high cost, unsuitability for some patients (those who are obese, have pacemakers, or have renal failure), the potential for unnecessary biopsies, lack of portability and the length of time required for imaging.

Table 8. Concordance between BI-RADS® assessment categories and management recommendations

Assessment	Management	Likelihood of Cancer
Category 0: Incomplete – Need additional Imaging Evaluation	Recommend additional imaging: mammogram or targeted US	N/A
Category 1: Negative	Routine breast MRI screening if cumulative lifetime risk $\geq$ 20%	Essentially 0% likelihood of malignancy
Category 2: Benign	Routine breast MRI screening if cumulative lifetime risk $\geq$ 20%	Essentially 0% likelihood of malignancy
Category 3: Probably Benign	Short-interval (6-month follow-up)	$\geq$ 0% but $\leq$ 2% likelihood of malignancy
Category 4: Suspicious	Tissue diagnosis	>2% but <95% likelihood of malignancy
Category 5: Highly Suggestive of Malignancy	Tissue diagnosis	> 95% likelihood of malignancy
Category 6: Known Biopsy-Proven Malignancy	Surgical excision when clinically appropriate	N/A

4. COMPUTERIZED TOMOGRAPHY SCAN (CT SCAN)

A computed tomography (CT or CAT) scan is not routinely used for breast cancer screening or diagnosis, but can be useful for contrast-enhancing lesions and lesions close to chest wall (contrast enhancing lesions suggest malignancy) (Figures 37, 38, 39). CT scan is routinely used to assess for chest, liver, pelvic and bony metastases and post-treatment follow-up.

Figure 37. Breast mass in CT scan.

Figure 38. Breast cancer in Pre contrast CT scan.

Figure 39. Post contrast CT scan enhancing lesion (yellow arrow), suggesting malignancy.

5. POSITRON EMISSION TOMOGRAPHY (PET) SCAN

Most breast malignancies have greater metabolism than normal tissues and concentrate ^{18}F -fluorodeoxyglucose (FDG), the agent most widely used in clinical positron emission tomography (PET) scanning. [59, 60] Whole-body PET does not have the spatial resolution needed for breast imaging. PET/computed tomography has been shown to be useful in the

restaging of breast cancer, in evaluation of response to therapy, and as a problem-solving method. [59, 61] Small, dedicated PET scanners have been developed for breast imaging, which use gentle compression.

The radiopharmaceutical that is primarily used in the clinical evaluation of most cancers, including breast cancer, is FDG. FDG is widely available from commercial radiopharmacies and provides clinically important information relevant to cancer. Other radiopharmaceuticals, such as F-18 fluoroestradiol and F-18 fluoro-L-thymidine, are now being evaluated in breast cancer patients, but these radiopharmaceuticals have not assumed a clinical role at this time.

The FDG is administered intravenously in the arm opposite a known or suspected breast lesion or through a foot vein, because extravasation can result in axillary lymph node accumulation. Accumulation in an axillary lymph node could be from either metastatic disease or extravasation, so it is important not to inject in the arm on the side of the lesion. The patient should be comfortable and warm after administration of the FDG. Movement of the head and neck should be minimized to avoid accumulation in neck and shoulder girdle muscles. Furthermore, some evidence suggests that keeping the patient comfortably warm at the time of administration decreases accumulation in brown fat that may be confused with supraclavicular and internal mammary lymph node accumulation. For the evaluation of primary breast lesions, some authors have suggested the use of prone imaging and 3-hour delayed imaging.

In most studies of FDG-PET imaging in breast cancer (Figure 40), investigators have administered 10-20 mCi of FDG, and imaging is started 45-60 minutes after injection. Whole-body scans have included the external auditory meatus through the proximal thighs. Attenuation corrected scans are performed. It is unclear at this time whether 3-dimensional acquisitions will have an advantage over the 2-dimensional acquisitions that have been used until now. Furthermore, the advantages of the combined PET and computed tomography over dedicated PET scanners alone have not been demonstrated at this time.

A pilot study of positron emission mammography (PEM) by Taft et al. evaluated 44 images. PEM demonstrated 89% of the lesions. Multifocal disease was correctly ruled out in 17 of 17 cases. [62] Berg et al. found that PEM combined with mammography and sonography yielded 47 (98%) of 48 cancers. [8] Dense breasts do not appear to negatively affect PEM as they do mammography. Lower-grade tumors are more likely to be missed, which makes sense, as the technique employed in PEM is based on FDG concentration [59].

Positron emission tomography (PET) scans are one of the tests oncologists can use to establish a baseline of whether and to what extent your cancer may have spread to other parts of your body. The problem with PET scans is that they are not very accurate, because they are not very good at finding small cancer spots. In the past, tumor needs to be at least 2cm to be seen on the scan. There are now newer scans that are a bit better and they can detect virtually all 2 cm lesions. However, they can only detect about one-third of those that are smaller than 1 cm. This means they can result in a false negative result. In addition, they often give false positive results, indicating that something might be cancer when it is really an inflammation, infection, or cells that happen to be growing rapidly.

In a prospective study that evaluated the accuracy of PET in axillary nodal staging in 360 women with newly diagnosed breast cancer, PET had a 61% sensitivity and 80% specificity. [63] Patients with small nodal metastases and with only a few lymph nodes involved have their conditions missed on PET scans. PET is not accurate enough to replace the sentinel lymph node study. In a study that evaluated the impact of the site of the primary breast

cancer, patients having inner quadrant primary cancers had a much greater frequency of extra-axillary metastases than did patients having outer quadrant primaries and were twice as likely to have progression of their disease.

Several studies have evaluated the accuracy of FDG-PET in detecting primary breast cancer. A meta-analysis of the PET literature that included 606 patients demonstrated that PET had a sensitivity of 88% and a specificity of 79%. [64] The mean tumor size included in these studies ranged from 2-4 cm in diameter. Most false-negative results relate to small lesions (<1 cm), low-grade malignancy, and noninvasive cancers. False-positive results occur primarily from infectious or inflammatory lesions, such as mastitis and hemorrhagic inflammation after biopsy or surgery.

Figure 40. Invasive ductal carcinoma in PET scan (arrow).

PET in Lymph Node Staging

The evaluation of the axillary lymph nodes is important for determining prognosis (Figure 41). The 10-year survival of patients with negative axillary lymph nodes is 65% to 80% and is significantly greater than in patients with 1-3 nodes, who have a 38% to 63% 10-year survival, and in those patients with more than 3 axillary nodes, who have a 13% to 27% 10-year survival. [65] Axillary lymph node involvement influences the selection of treatment. Clinical evaluation, including conventional imaging, is not accurate in detecting axillary nodal disease. Sentinel lymph node localization is performed using Tc 99m-labeled colloids and/or blue dye in patients with invasive cancers that are 2 cm or less in diameter. Most of these patients (>80%) have negative axillary lymph nodes at surgery. Axillary nodal surgery has well-known risks, including lymphedema and diminished upper extremity motility and functioning. Metastases to the internal mammary lymph nodes have similar prognostic significance and occasionally are the only site of metastatic disease. The internal mammary lymph nodes are typically not assessed pathologically because of the extensive surgery required to sample these nodes. FDG-PET imaging has been used to evaluate whether it can replace or supplement the information available for lymphoscintigraphy and axillary lymph node staging. Several studies have evaluated FDG-PET for the detection of axillary metastatic disease. These studies have generally shown sensitivity between 50% and 100% and specificities between 67% and 100%. PET has minimal impact on patients with palpable axillary lymph nodes, because these patients will undergo axillary dissection. Thus, it is

important to consider the patients with nonpalpable lymph nodes. A meta-analysis of FDG-PET has demonstrated that it has a 95% sensitivity and an 88% specificity for palpable axillary lymph nodes compared with the 90% sensitivity and 94% specificity in patients having nonpalpable lymph nodes [64].

Figure 41. Breast cancer metastasis in internal mammary lymph node in PET scan (arrow).

Wahl et al., [66] performed a prospective study of axillary nodal staging. This study included 360 women with newly diagnosed breast cancer. The FDG-PET images of the draining nodal regions were interpreted qualitatively and qualitatively in a blinded manner by 3 experienced readers. The results from 308 assessable axillae were compared with axillary node pathology to determine the accuracy of the PET findings. The prevalence of axillary nodal metastases was 35%. The mean estimated area under the receiver operating characteristic curve for the 3 readers was 0.74. When at least 1 abnormal axillary focus was identified, the sensitivity was 61%, specificity was 80%, positive predictive value was 62%, and negative predictive value was 79%. False-negative results were obtained in patients who had smaller and fewer lymph nodes. The use of the standardized uptake value (SUV) normalized to lean body mass showed a positive predictive value of 90% and a sensitivity of 32% at an SUV of 1.8 or greater. If two or more foci of abnormal accumulation were noted, the predictive accuracy was 78% to 83%, but at a sensitivity of only 27%. The authors conclude that PET is not recommended for routine staging of the axilla in most patients with newly diagnosed breast cancer.

PET in Distant Metastatic Disease

In addition to detecting the primary breast cancer and loco-regional metastases, whole-body FDG-PET can detect distant metastatic disease to the soft tissues, viscera, and bone. FDG-PET imaging has been shown to be accurate for the detection of distant metastatic disease. In a study by Dehdashti and colleagues, [67] PET had a sensitivity of 89% and specificity of 100% for differentiating benign from malignant lesions. PET has been shown to identify metastatic disease that is not detected by conventional imaging. A study by Schirrmeister and colleagues [68] evaluated 89 patients with breast cancer undergoing initial staging. FDG-PET detected distant metastatic disease in 7 patients, 3 of whom had negative

conventional imaging study results. Four patients had false-positive bone scintigraphy and true-negative PET scan results.

Tran and colleagues [69] evaluated the frequency of extra-axillary metastases in the absence of axillary involvement in breast cancer patients with outer quadrant primary lesions and compared this frequency with that of inner quadrant breast cancers. Their study included 141 breast cancer patients, with 42 having inner quadrant lesions and 99 having outer quadrant lesions. The patients underwent a 3-year postscan and clinical follow-up. The patients with inner quadrant cancers had a 6-fold greater frequency of PET findings of extra-axillary metastasis compared with patients who had outer quadrant cancer. The patients with inner quadrant disease were twice as likely to experience progression of their disease as were patients with outer quadrant lesions.

Bone metastases are major contributors to the morbidity of breast cancer. The median survival of patients with metastatic disease to bone is 24 months. [70] Bone scintigraphy, the primary modality used for evaluating skeletal metastatic disease in breast cancer, has a low specificity and sensitivity for detecting osteolytic lesions. FDG-PET has been demonstrated to be more sensitive than bone scintigraphy. The FDG-PET scan is more accurate in detecting osteolytic lesions than osteoblastic lesions [71].

PET in Monitoring Therapeutic Response

The only cancer that Medicare has approved coverage for therapeutic monitoring is breast cancer. The assessment of response to therapy in patients with advanced breast cancer is important because preoperative therapy predicts outcome. Patients who respond to the chemotherapy or hormonal therapy have a better prognosis than patients who do not respond. Schelling and colleagues, [72] in a study of 22 patients with locally advanced breast cancer, demonstrated that PET correctly identified responders from nonresponders with a sensitivity of 100% and specificity of 85%. Response was defined as a decrease in the tumor SUV to less than 55% of the baseline value.

SPECT-CT Scan

SPECT-CT is where two different types of scans are taken and the images or pictures from each are fused or merged together. The fused scan can provide more precise information about how different parts of the body function and more clearly identify problems such as breast tumours. Single photon emission computed tomography (SPECT): SPECT images are obtained following an injection of a radiopharmaceutical that is used for nuclear medicine scans. The injected medication sticks to specific areas in the body, depending on what radiopharmaceutical is used and the type of scan being performed.

The radiopharmaceutical is detected by a nuclear medicine gamma camera. The camera or cameras rotate over a 360 degree arc around the patient, allowing for reconstruction of an image in three dimensions. CT scanner rotates much faster than the gamma camera, so the CT part of the study takes less time than the SPECT study.

The similarity between SPECT and CT in the method of image processing allows the images to be combined.

Preoperative imaging technologies such as scintigraphy or, recently, SPECT/CT may contribute to the precise localization of the SLN(s) and support surgical planning. [74, 75] Fluorescence imaging systems, mini gamma cameras and freehand SPECT (FhSPECT) have been suggested as alternatives that allow image-guided resection of the SLN. The first two technologies provide 2-D images of either fluorescent or radioactively labelled SLNs, [76-78] but none of the technologies has yet found its way into clinical routine. The FhSPECT technology was developed by a joint research group of the Faculty of Computer Science and the Faculty of Medicine at Technische Universität München and utilizes 3-D images, thus providing additional depth information and the possibility of image fusion with a live video of the operation sites (Figure 42) [79].

Figure 42. Patient with SLN (arrows) in the left axilla: a. preoperative scintigram; b. pre-incision FhSPECT image; c. postoperative FhSPECT image with no remaining activity (stars injection site).

FDG-PET plays an important role in the evaluation of patients with breast cancer. Its role in the detection of primary breast cancer is still under evaluation. FDG-PET is useful in the initial staging and restaging of patients with locally advanced breast cancer. FDG-PET scanning is not accurate enough to replace sentinel lymph node studies for the evaluation of axillary nodal involvement. FDG-PET scanning is rapidly becoming a critical method for monitoring response to therapy in patients with locally advanced breast cancer [73].

6. SCINTIMAMMOGRAPHY

Another form of breast imaging that involves the functional uptake of radiotracers is scintimammography. It uses ^{99}Tc sestamibi, which is taken up by breast cancers. A dual-head machine was tested at the Mayo Clinic, which studied more than 900 patients in 6 years. [59] The machine functions independent of breast density. Heavy compression of the breast is not

required. They found a 97% concordance with mammography. Medicare charges are estimated at \$1,029.69 for MRI and \$292.12 for scintimammography. The final sensitivity is over 90%, making this a useful adjunct to mammography. [80] As these are emerging technologies that are not yet widely used, clinical data are still scarce.

Guidelines for Breast Cancer Screening

The American Cancer Society (ACS) guidelines for breast cancer screening currently recommend that for average-risk women mammographic screening begin at age 40 years and continuing for as long as a woman is in good health. Breast self-exam (BSE) is an option for women starting in their 20s. Women in their 20s and 30s should have a clinical breast exam every 3 years. Women over 40 years of age should have a clinical breast examination yearly. Women should be told about the benefits and limitations of breast self-examination and the importance of prompt reporting of any new breast symptoms. As long as a woman is in reasonably good health and would be a candidate for treatment, she should continue to be screened with mammography.

For women at high risk, earlier initiation of screening, shorter screening intervals, or the addition of other modalities may provide benefit. It recommended annual MRI screening in addition to mammography for BRCA mutation carriers; first-degree relatives of BRCA carriers who are untested and those patients with a calculated lifetime risk of 20% to 25% or greater as defined by BRCAPRO or other models that are largely dependent on family history. MRI is also recommended for patients who received radiation to their chest between age 10 and 30 years, patients with Li-Fraumeni syndrome and their first-degree relatives, and patients with Cowden and Bannayan-Riley-Ruvalcaba syndromes and their first-degree relatives.

Life expectancy continues to increase, and in developed countries women aged 75 years and older represent an increasing percentage of the population. Evidence-based guidelines for the regular screening of older women are lacking. Patients with life expectancies less than 5 years are not likely to derive any survival benefit from cancer screening. However, age in itself should not be a reason to stop screening but rather the patients overall health and ability to receive treatment and benefit from the screening.

ABSTRACT

Sir Godfrey N. Hounsfield (28 August 1919 – 12 August 2004) was an electrical engineer who in 1979, together with Allan McLeod Cormack, received the Nobel Prize in Physiology or Medicine for developing the diagnostic technique of X-ray computed tomography (CT) [1]. The first CT scanners were designed exclusively for brain CT, and in 1972 a female with a suspected brain tumor was the first patient examined using CT scanning. In the next year, the first publication of brain CT imaging was true [2]. Early CT scans were of limited quality and demanded long scanning and processing times. Nevertheless, the following development of CT scanning provided neuroradiology with much better brain tumor images and revolutionized neurosurgical practice. A new era in modern neurosurgery had commenced [3]. The MRI, on the other hand, has literally transformed the status of neuroimaging by bringing most of the structural details of the brain and spinal cord in front of our eyes. The most important applications of the modern neuroimaging modalities in neurosurgical practice are presented in this chapter.

IMAGING IN NEUROSURGICAL ONCOLOGY

A. Brain Tumor Imaging

1. Computed Tomography

The decrease in number of the air studies, angiograms, and nuclear scans in detecting brain tumors is documented by an article from Mayo Clinic published in *Radiology* in 1975

* Corresponding Author's Email: grigo@auth.gr.

[4]. In the next article of the same *Radiology* issue, the application of contrast media administration in brain tumor imaging depicted that more than 80% of intracranial mass lesions enhanced [5]. *Enhancement* is a phenomenon caused by the disruption of the tumor vasculature's blood-brain barrier (Figure 1). Following the administration of contrast agent, there is an increased difference in an imaging characteristic between a lesion and the surrounding normal tissue due to the passage of contrast agent within the tumor's interstitium [6]. Correlation of contrast enhancement to astrocytoma grade was documented in 1978 [7]. CT has evolved over the years, with improvement of image quality, reduction of scan times and cost.

Figure 1. Enhancement of brain tumor after contrast agent administration.

Brain tumors may be *hypodense*, *isodense* or *hyperintense* to gray matter correlating to tumor histology and location. Small or isodense brain tumors may not be depicted on non-contrast CT scan, but they may be delineated after contrast media administration. Despite the

advent of Magnetic Resonance Imaging (MRI), CT is still not only appropriate, but also necessary for emergent imaging.

CT is superior to MRI in depiction of *calcification* within brain tumors. Oligodendrogliomas, ependymomas, gangliogliomas, choroid plexus papillomas, astrocytomas, central neurocytomas and metastases are the intra-axial brain tumors that more often present calcifications. Extra-axial tumors that have calcifications are craniopharyngiomas, meningiomas, chondrosarcomas and chordomas. Additionally, CT contributes to detection of *osseous changes* secondary to brain tumor.

Hemorrhage which is characteristic of oligodendroglioma, glioblastoma multiforme, and metastases from melanoma, breast and lung cancer, is readily evaluated on CT scans.

Fat presents characteristic negative HU values on CT and is encountered in lipomas, teratomas and dermoid cysts.

Last but not least, patients suffering from claustrophobia, with metallic devices or pacemakers, critically ill or unstable benefit from CT exams [6].

Perfusion CT

Perfusion CT (PCT) is an imaging technique that is usually applied in the evaluation of patients with acute brain infarct. Additionally, PCT has been used during the previous years as an imaging biomarker with parameters such as tumor blood volume, blood flow, vascularity permeability, and size of extravascular extracellular space that are applied to patients with brain tumor [8-10]. Data obtained by PCT is used for tumor grading and prognosis, as well as for estimation of the response to antiangiogenic agents.

Perfusion CT consists of acquiring sequential CT images during the wash-in and washout of an iodinated contrast agent through the brain tissue. Following the rapid administration of a contrast medium bolus and serial image scanning at short intervals, maps of perfusion parameters are obtained:

- a) Cerebral blood volume (CBV)
- b) Cerebral blood flow (CBF)
- c) Mean transit time (MTT), and
- d) Permeability surface-area product maps [11-13]

PCT is able to differentiate low- and high-grade gliomas presenting high sensitivity and specificity [11]. Additionally, PCT can distinguish enhancing grade III from grade IV astrocytic tumors and delineate heterogeneity of gliomas [10].

PCT can be useful in differentiating gliomas from tumefactive demyelinating lesions, mass-like lesions of vasculitis or angiopathy and lymphoma, as well as in distinguishing recurrent tumor from radiation necrosis [12].

It has also been demonstrated that metastases from different primaries can be distinguished from one another using CT perfusion in the majority of cases [14].

Finally, it is worth pointing out that PCT provides absolute quantification of perfusion parameters and has no susceptibility artifacts due to hemorrhage, which may be present in post-operative patients [13].

2. MRI Techniques

MR Perfusion

Perfusion imaging permits insight into angiogenesis, a process essential for neoplastic growth [15]. Angiogenesis leads to development of tumoral neovasculature that commonly exhibits increased endothelial permeability [16]. Neoplastic vessels are abnormally structured vessels that tend to be leaky, and thus neoplasms have *increased permeability parameters* [15].

Perfusion is the process by which nutrients and oxygen are delivered to tissue and metabolic products are removed by blood flow.

Perfusion MRI provides measurement of the parameters of cerebral microvascularisation:

- a) Regional blood volume (RBV)
- b) Mean transit time (MTT), and
- c) Regional blood flow (RBF)

Measurement of tissue perfusion depends on the ability to serially measure concentration of a tracer agent in a target-organ of interest [17].

MR perfusion is based on the use of a tracer that may be *exogenous* or *endogenous* (spin labeling).

Imaging techniques acquired with exogenous contrast agents are dynamic susceptibility contrast (DSC) MRI and dynamic contrast enhanced (DCE) MRI.

Endogenous tracer MR perfusion takes advantage of signal loss resulting from magnetically labeled water protons flowing into the imaging plane and exchanging with tissue protons. Water protons within inflowing arterial blood are magnetically labeled (“tagged”) by the application of a special radiofrequency pulse [17]. Arterial spin labeling (ASL) MRI is a routine endogenous tracer MR perfusion sequence.

CBV calculated by DSC-MRI is strongly correlated to tumor grade [18-20]. Areas of malignant transformation or tumor dedifferentiation in low-grade lesions at risk before they are visible on conventional MRI can be depicted, allowing accurate targeting of biopsies, and potentially more accurate estimation of tumor grade [23].

Astrocytoma rCBV is strongly correlated to astrocytoma grading but this should be limited to fibrillary astrocytomas because other gliomas (especially oligodendrogliomas) may present high rCBV despite grade [18, 22, 23]. Oligodendrogliomas are characterized by delicate neoangiogenic vessels (“chicken-wire” vasculature) and *even low-grade oligodendrogliomas present elevated rCBV that may be as high as in glioblastoma* [23].

Lymphoma can be differentiated from primary high-grade neoplasms and high-grade glial neoplasms on MRI perfusion parameter basis [24, 25].

Metastatic brain tumors contain capillaries that resemble the organ where the systemic cancer arose and not those of the brain [26].

Discrimination between high-grade glioma and metastatic brain lesion can be provided by examining the peritumoral lesion where the differences in mechanisms underlying peritumoral edema affect microvasculature [27]. Higher CBV values are documented around high-grade gliomas as compared to around metastases [24].

Regional changes in MR perfusion parameters that occur early during treatment can be used to construct a paramagnetic response map, which can predict overall survival in high-grade glioma, and may even distinguish pseudoprogression in temozolomide-treated glioblastoma multiforme [28, 29].

MRI perfusion techniques can differentiate between tumor recurrence (high CBV) and radiation necrosis (low CBV).

Diffusion Weighted Imaging

Diffusion weighted imaging is an MRI method that is sensitized to the random motion of water molecules in all directions ('Brownian motion'). Random water motion is not possible in various pathologies and this is called "restricted diffusion". Lesions are characterized according to the presence of unrestricted or restricted diffusion. Lesions with restricted diffusion present high signal on diffusion weighted images while they are hypointense on Apparent Diffusion Coefficient (ADC) maps [30].

ADC is inversely proportional to cellular density and reflects the intensity of diffusion of water molecules in a tissue and ADC maps quantify the degree of water molecule mobility.

Although initial reports between minimum ADC and glioma grade were promising, there is a significant overlap in ADC values among different grades of glioma [31].

Metastatic cerebral neoplasms present an elevated ADC. There is an overlap of ADC values between primary and secondary brain tumors. Measuring ADC values in peritumoral regions can differentiate primary (high ADC) from secondary (low ADC) brain tumors [32].

Medulloblastoma, lymphoma and meningioma present low ADC values. A necrotic tumor presents high ADC value whereas an abscess has low ADC value.

Also, an arachnoid cyst (low ADC) can be distinguished from an epidermoid (high ADC).

MR Spectroscopy

MRS is the only noninvasive technique that measures chemicals within the body. MRS distinguishes metabolites according to their slightly different chemical shifts or resonance frequencies [33]. Proton MR spectroscopic imaging (^1H -MRSI) incorporates spatial localization of MRI with biochemical data of ^1H -MRSI [34].

Brain tumors present different spectra from normal brain tissue. Choline (Cho, 3.24ppm) signal is elevated in nearly all tumor types due to alteration of membrane metabolism. Cho is a basic component of the cell membrane and contains contributions from Cho-containing compounds involved in membrane synthesis and degradation [35]. Cho also correlates with cellular density of the tumor [36], cell proliferation, and with degree of tumor infiltration into brain tissue [37]. *N*-acetyl-aspartate (NAA, 2.02 ppm) is a marker of neuronal activity.

NAA decreases due to loss, dysfunction, or displacement of normal neuronal tissue [38]. In almost all brain tumors, NAA signal is decreased and Cho signal often increased (increase of Cho/NAA ratio).

The Cr signal is the sum of Cr and phosphocreatine. Cr is associated with short-term energy storage and is decreased when there is rapid cell proliferation [34]. Lactate (Lac) is not normally encountered in the adult brain and is a marker of anaerobic glycolysis [39]. The presence of lipids has been correlated with necrosis where cellular death results in membrane breakdown [40]. Increased levels of myo-inositol (ml) reflect increase of glial cells. The most

useful parameters in MRS for the diagnosis and differential diagnosis of brain tumors are the following ratios: Cho/Cr, Cho/NAA, and NAA/Cr.

MRS, in combination with conventional MRI imaging, can aid to differentiate a tumor from a non-neoplastic lesion (Figure 2). Non-neoplastic lesions that mimic a tumor may be infectious (abscess), ischemic, or demyelinating (tumefactive demyelination) [35]. Some non-neoplastic lesions may present elevated Cho, making differential diagnosis difficult. For example, increased Cho, often increased lactate and decreased NAA can be found not only in brain tumors but also in acute demyelination lesions [41].

MRI is the most sensitive imaging modality for the detection of brain tumors. However, it lacks specificity as different lesions may share similar MR features.

Studies have suggested the correlation of tumor grade to Cho levels, implying that higher-grade tumors have greater Cho concentrations [42]. However, some high-grade tumors due to necrosis may present lower Cho levels than lower grade tumors. Heterogeneous tumors with central necrosis and proliferative rims, and invasion of surrounding brain tissue reflect metabolic heterogeneity also. ^1H -MRS is useful in studying changes in metabolic profile during the malignant transformation from diffuse to anaplastic astrocytoma [34].

Figure 2. MR spectroscopy. The values of Cho, Cr and NAA are depicted.

MRS should be anticipated as an adjunct imaging modality that may aid to differential diagnosis rather than a modality diagnosing the exact type of a brain tumor on its own.

Investigation of peri-enhancing tumor regions can facilitate discrimination of solitary metastases from primary brain tumors. As gliomas are infiltrating lesions, Cho is elevated in surrounding tissue. On the contrary, as metastatic lesions tend to be more encapsulated, surrounding tissue does not demonstrate high Cho levels [43].

MPS can significantly aid the differential diagnosis between abscess and neoplasm. The acquisition of a single-voxel spectrum with short TE, besides the low Cho signal, will detect the presence of other minor peaks not encountered in neoplasia (e.g. succinate, acetate, leucine, alanine) [44].

In the study of Crawford et al. [45] GBM patient survival was studied in correlation to pre-surgical metabolic and physiological parameters. Survival was poor in patients with large areas of contrast enhancement, restricted diffusion, and abnormal metabolism. Survival time was also negatively associated with high lactate and lipid levels and the ADC in the enhancing area. Metabolic indices however have not always been proven to be prognostic in survival prediction in other brain tumors.

Total resection of the brain tumor is the basic goal in neuro-oncology. However, high-grade gliomas have indistinct boundaries and infiltration. MRS can aid proper tissue sampling at brain biopsy. Areas of increased angiogenesis, vascular permeability, and high metabolic activity should be sampled [46].

The dilemma between recurrent tumor and radiation necrosis, a focal reaction to radiation in patients undergoing radiation therapy, is common. Radiation necrosis demonstrates T2-hyperintense signal and enhancement after contrast medium administration, findings that are difficult to differentiate not only from tumor progression, but also from pseudo-progression (increase in edema, mass effect, and contrast enhancement that resolves over time) [47]. Increased Cho signal is indicative of recurrence whereas reduced Cho levels indicate radiation necrosis [48]. MRS cannot differentiate between tissue containing mixed tumor-radiation necrosis and either tumor or radiation necrosis, although it did achieve good separation between pure necrosis and pure tumor [49].

Functional MRI (fMRI)

The functional magnetic resonance imaging (fMRI imaging) is a non-invasive neuroimaging technique that can be used for studying the function of the human brain in vivo. The fMRI technique extends the use of classical MRI imaging beyond the anatomical information and provides information about the biological function. The study of the functional organization of the brain was the main interest of researchers since the late 19th century. In 1881 the Italian physiologist Angelo Mosso observed that the neural activity of a human is associated with the local brain cerebral blood flow (CBF). A few years later similar observations have been made by Charles Roy and Charles Sherrington in lab-animals. Unfortunately the objections of other researchers and the lack of sufficient experimental means led to a decrease in interest in this observation. It was not until half century passed that this observation came forth again, when researchers proved that the oxygenated hemoglobin is repelled, while the deoxyhemoglobin is attracted by magnetic fields. This phenomenon was used by Seiji Ogawa in order to prove that with the technique of imaging the oxygen level of blood [Blood Oxygenation Level Dependent imaging] (BOLD imaging), one can visualize the brain function. This is a standard technique used to create images in functional magnetic resonance imaging studies (fMRI) and is based on differences in cerebral blood flow in brain regions that show increased activity. The first successful attempt to elucidate the functional organization and mapping of the brain using magnetic resonance carried out in 1991 in the MRI center of the Massachusetts General Hospital in Boston. After that, identifying brain areas activated during a specific test offered a very satisfactory level of spatial resolution of 2 mm and a degree of temporal resolution of few seconds.

Blood flow to the brain is locally controlled and is in response to oxygen and carbon dioxide of the cortical tissue. When an area of the cortex increases its activity in response to a process, initially there is a fall of oxygenated hemoglobin (oxyHb) and an increase in deoxygenated hemoglobin (deoxyhemoglobin, deoxyHb). After a delay of 2-6 seconds, the cerebral blood flow (CBF) increases by providing an excess of oxygenated hemoglobin, replacing deoxyhemoglobin. This increase in local tissue oxygenation can be imaged. The reason that the fMRI is able to detect this change is due to a fundamental difference in the paramagnetic properties of oxyhemoglobin (oxyHb) and deoxyhemoglobin (deoxyHb), whereas the latter is paramagnetic, while the first is not. However, there are some limitations of BOLD imaging and other CBF imaging techniques. Therefore, i) cerebral blood flow is only an indirect indicator of activity, rather than direct visualization of cortical activation, ii) the smallest unit of the brain that is able to regulate its blood flow, it is measured in millimeters in diameter and finally iii) the increase in blood flow is in conjunction with the increase of the activity having a 2-6 seconds delay.

Statistical analysis of data obtained from BOLD technique is important and crucial for brain mapping with functional MRI. Thanks to wide range of experiments done with fMRI several statistical models and approaches can be applied in order to extract useful information. The simplest statistical model data analysis of BOLD technique is the t-test where the statistical parameter taken into consideration is the p-value, which reflects the level of confidence. The proposed p-value is $p < 0.05$ with a confidence level of 95%. Moreover, the selection of a certain threshold is equally important for the sensitivity of the signal that is to be received. The goal is not to identify the voxels that have a signal greater than the threshold, but to identify those voxels whose change of signal is much larger than expected and the level of statistical significance depends on the threshold applied according to predefined statistical parameters. Data analysis is done by software that processes the data of anatomical images and of fMRI. Before that, images of fMRI are aligned (alignment), normalized (normalization), smoothed and motion-corrected. Then statistical analysis is applied after using a threshold in signal sensitivity and the results of fMRI are displayed on high-definition three-dimensional anatomical images. The representation of functional areas is in accordance with a chromatic scale and the intensity of the signal is proportional to the threshold. The signal from brain activity is subtracted from the signal at rest. Changes in signal intensity are represented by the number Z , which is defined as:

$$Z = \frac{\text{average signal difference}}{\text{standard deviation}}$$

Low values of Z generate results of low resolution and specificity. High values of Z allow visualization of areas with high signal and have high resolution. Thus, setting this statistical parameter is depended on the signal intensity.

The idea of mapping functional areas of the brain for a safe navigation during a brain surgery is dated in the middle of 20th century. Although invasive techniques, such as transcortical stimulation, are a gold standard in functional neurosurgery, they do not allow the preoperative designing of the surgery, whilst neuropsychological tests do not offer precision. Thus, the need for an accurate preoperative technique in order to design and execute as safely as possible a brain surgery, has brought in the use of fMRI. Brain mapping is done in order to identify and surgically preserve eloquent areas such as motor speech area, sensorimotor

cortex, motor cortex and other brain areas that are responsible for writing, calculating, spatial perception, memory etc. Moreover brain mapping helps individualize an operation offering maximum surgical result. Consequently, fMRI contributes not only to the preoperatively design and to a safe neuronavigation during surgery, but it is also established as a decision-making examination for surgery. Finally, fMRI is widely used in neuroscience contributing to research, studying anatomy as well as brain diseases.

Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) consists a rapidly growing area of research, as well as clinical application in intracranial tumors [50]. DTI is the only non-invasive *in vivo* method for mapping white matter tract in the human brain [51]. DTI is based on the concept of *anisotropic diffusion*. Water diffusion in the white matter is not equal in all 3 dimensions but tends to move along the long axis of the fiber bundle because myelin sheath allows less water diffusion perpendicularly [50, 51]. The portion of overall diffusion that is therefore directional is referred as fractional anisotropy (FA) [52] and permits visualization of white matter fiber direction. FA maps quantify changes in FA values as loss of brightness (gray scale) and direction of white matter tracts in color: fiber orientation is represented by different colors. Diffusion-based MRI tractography is an imaging tool that generates 3-D reconstructions of white matter fiber tracts as an aid to identifying safe margins of resection [53]. DTI can evaluate the relation of a brain tumor to the adjacent white matter tracts [54, 55]. White matter involvement by a tumor can be deviated, infiltrated, edematous and destroyed. DTI contributes to planning for brain tumor surgery as it indicates white matter tracts relative to the tumor.

B. Spinal Tumor Imaging

Tumors of the spine compose a vast group of lesions that are derived from diverse tissues: neoplasms from the spinal cord, the leptomeninges, extradural soft tissues, primary and metastatic bone lesions as well as paraspinal soft tissue tumors. This long list of tumors is usually categorized according to the site of origin [56].

CT consists the method of choice for delineating osseous involvement, calcifications and the degree of bone loss [57]. CT can demonstrate tumor destruction. Multidetector CT obtains axial, sagittal, and coronal reformatted images [57].

Bone metastases are the most common neoplasms of the spine. Spinal bone metastases consist the most common site of bone metastasis. Vertebral metastases are the cause of initial presentation of symptoms in a significant group of patients with cancer. Vertebral metastases are located at the lower thoracic, lumbar and, at a lesser degree, at the cervical spine.

Vertebral metastases originate from cancer of the breast, lung, prostate, gastrointestinal system and thyroid gland.

Osteolytic metastases present low signal on T1 and high signal on T2 images (Figure 3). Contrast media should be administrated at the end of basic sequences because the enhanced bone metastasis may be impossible to differentiate from the surrounding vertebra.

Osteosclerotic metastases are depicted with low signal on both T1 and T2 images.

Figure 3. Metastatic spinal tumor with characteristic low signal on T1WI and high signal on T2WI.

In cases of spinal involvement in leukemia, bone marrow presents low T1 signal and intervertebral discs seem bright (“bright disk sign”).

Hemangioma is the most common benign vertebral lesion. Hemangiomas are mainly located at the lower thoracic and lumbar spine. T1 signal is high or low according to ratio of vascular to fatty component of the lesion. Hemangiomas have saturation of high signal on STIR sequences.

Osteoid osteoma is a benign lesion with characteristic CT features.

MRI is the most sensitive imaging method for evaluation of the spinal cord. Infiltration of nerve roots, thecal sac, paraspinal soft-tissues as well as vertebral bone marrow is markedly revealed [58].

Spinal tumors are classified as intradural (intra-medullary and extra-medullary) and extradural (epidural and from the vertebral column) (Figure 4).

There are 3 significant features in MRI images while evaluating patients suspected of having an intramedullary spinal lesion: cord expansion, degree of enhancement, and the presence of a cyst [58].

Ependymoma is the most common intramedullary spinal tumor in adults [60]. Myxopapillary ependymoma consists a rare, variant type of ependymoma, usually without connection with the spinal cord. Cord ependymomas occur most commonly in the cervical spine. Most spinal cord ependymomas are iso- or hypo- intense on T1 images. Rarely, they may present hyperintensity on T1 due to hemorrhage. On T2 images, ependymomas may be hyperintense or isointense.

Astrocytoma has poorly defined margins and is iso- to hypointense on T2 and hyperintense on T2 images. A degree of contrast enhancement is depicted. Cyst is a common finding. In more than half cases, astrocytoma is eccentric within the spinal cord [59].

Figure 4. Cervical MRI showing an intradural extramedullary tumor (meningioma).

C. Intraoperative MRI

Ferenc Jolesz at the Brigham and Woman's Hospital in Boston in 1990 first conceived the idea of operating under real MRI guidance. Intraoperative MRI (ioMRI) can identify any residual tumor, delineate the degree of brain shift and update the neurosurgical navigation system [61].

Additionally, potential intracranial complications such as hemorrhage, hydrocephalus and cerebral edema could be depicted [62].

In the first reports of patients in which ioMRI data was used, the image quality was able to identify residual tumor in most cases [63].

Low-field ioMRI in the following years however was not able to efficiently depict residual tumor, especially low-grade glioma [64, 65].

High-field ioMRI enhances the extent of resection, even for non-enhancing gliomas [66].

In high-field ioMRI, operations are performed using conventional, non-MR compatible equipment. The disadvantage however is that more time is required to obtain a scan and real-time imaging is unavailable [61].

Other distinct advantages of ioMRI include the excellent soft tissue discrimination, the ability to view the surgical site in three dimensions, and the ability to "see" tumor beyond the surface visualization of the surgeon's eye. The enhanced ability to view the tumor being

biopsied or resected allows the surgeon to choose a safe surgical corridor that avoids critical structures, maximizes the extent of the tumor resection, and confirms that an intraoperative hemorrhage has not resulted from surgery [67].

CT AND MRI IN THE EMERGENCY DEPARTMENT

A. Craniocerebral Injuries

CT is the preferred method for evaluating patients after traumatic CNS traumatic injuries. The principal tool for imaging severe acute craniocerebral trauma is the Multidetector Computed Tomography (MDCT). It is used for the detection of:

- a) Intracranial hemorrhage
- b) Mass effect
- c) Cerebral contusions
- d) Cerebral edema and herniation
- e) Skull fractures (Figure 5)
- f) Displaced bone fragments
- g) Foreign bodies
- h) Intracranial air

Figure 5. Cranial CT after 3-D reconstruction. Depressed skull fracture (frontal bone).

MRI is relatively insensitive for the detection of skull fractures and small bone fragments [68, 69]. However, the role of MRI is growing in the assessment of acute, subacute and chronic phase of craniocerebral trauma. MRI is more sensitive than CT to certain injuries like:

- a) Diffuse axonal injury (DAI)
- b) Small extra-axial fluid collections
- c) Cortical contusions, and
- d) Brainstem injuries [70]

In the acute or subacute phase of trauma:

FLAIR sequence presents high sensitivity for DAI, edema, subarachnoid and intraventricular hemorrhage [71].

Gradient echo T2* and SWI sequences are sensitive for detection of DAI, intracranial hemorrhage and blood degradation products with paramagnetic properties.

DWI-ADC map sequences are useful in the evaluation of DAI, cytotoxic edema and hypoxic-ischemic brain damage in cases of non-accidental head injury (e.g. child abuse) [72, 73].

Finally, MRI using a complex variety of sequences can provide data about the “age” of an intracranial hemorrhage.

As a general rule, MRI is indicated in stable patients in whom there is a significant discrepancy between the patient’s clinical condition and CT findings [68, 74].

In the chronic phase of trauma:

MRI is superior to CT for the detection of chronic subdural hematomas (CSH), which are often isodense to CSF on non-contrast CT scans.

FLAIR and Gradient echo T2* sequences are superior to T2 sequence in the detection of small subdural hematomas, with different signals due to varying phases of the blood-breakdown process.

Gradient echo T2* and SWI sequences demonstrate hypointense hemosiderin deposits after DAI.

Post-traumatic encephalomalacia and gliosis are much better appreciated with FLAIR sequence. On FLAIR, the area of tissue loss is isointense to CSF and is surrounded by a rim of gliosis that is hyperintense.

B. Spine Injuries

MR imaging has supplanted CT as the modality of choice for the majority of CNS conditions including neoplasms and vascular lesions. However, in some instances, CT provides a diagnostic advantage for the evaluation of spinal pathology especially in evaluating spine-trauma patient. CT with multiplanar reformatted images and 3D-display remains the method of choice for the detection of fractures and their patterns, displacement or retro-pulsed bony fragments and narrowing of the spinal canal, information that is critical for the appropriate management of trauma victims (Figure 6).

The size, shape, integrity, as well as the degree of canal compromise are best assessed with CT. It is often the only modality to demonstrate subtle lesions especially small cortical

fractures, pars interarticularis defects, widening of the apophyseal joints, locked facets, occult fractures of the posterior elements and fractures of the occipital condyles [75, 76]. Evaluation also includes assessment of the disc, nerve root and paraspinal soft tissue including ligaments and evaluation of stability. When further evaluation of the cord and roots or an expanding extramedullary hematoma is indicated, MRI is preferable to CT, to reproduce the internal architecture of the spinal cord and the injured cord parenchyma.

Figure 6. Spine CT after 3-D reconstruction shows a traumatic vertebral fracture.

Except from the comprehensive display of spinal anatomy and pathology, CT can be performed with the same settings as CT for the other traumatic injuries of the body areas [77, 78]. In addition CT angiography is an accurate, rapid, noninvasive diagnostic alternative in the initial evaluation of patients who present to the emergency department with possible carotid and vertebral arterial injuries [79, 80].

IMAGING OF STROKE

Stroke can be defined as a sudden or rapid onset of a neurologic deficit due to a cerebrovascular lesion, lasting longer than 24 hours. If the neurologic deficit lasts <24 hours, it is called *transient ischemic attack* (TIA). There are four main etiologies for stroke:

- a) Cerebral infarction (80%)
- b) Intraparenchymal hemorrhage (ICH) (15%),
- c) Non-traumatic subarachnoid hemorrhage (SAH) (5%)
- d) Venous infarction (1%) [89]

Acute *ischemia* constitutes approximately 80% of all strokes and is an important cause of morbidity and mortality in the United States [81]. Stroke is the third leading cause of death in the USA, and cerebral infarction is the most common cause of disability among adult Americans [88].

Until recently, before effective therapies were introduced for acute ischemic stroke, imaging was used primarily to exclude “stroke mimickers”. There is a long list of conditions that mimic the symptoms of acute ischemic stroke, such as intracranial hemorrhage, neoplasms, infection, migraine, seizures, functional and metabolic disorders and vasogenic edema syndromes [88]. It is therefore very important to confirm that the cause is an ischemic lesion, before therapy is started, as these non-ischemic stroke mimickers should not be treated with thrombolysis.

The development of new treatment options, such as intra-arterial and intravenous thrombolysis, have led to the evolution of imaging technology in order to decide which stroke victim will benefit from the new therapeutic modalities [81]. The new aggressive therapies are aimed to re-establish the blood flow in the infarcted area, to reduce the size of the infarcted tissue and to protect the surrounding brain at risk, which is called the *penumbra*. Brain tissue is exquisitely sensitive to ischemia. In the complete absence of blood flow, the available energy can maintain neuronal viability for approximately 2-3 minutes. However, in acute stroke, ischemia is more often incomplete, because uninjured arterial and leptomeningeal vessels supply blood to the injured area of the brain [81]. Therefore, acute cerebral ischemia may result in an infarcted core, which is the ischemic region that is irreversibly injured, and the penumbra, which is defined as the brain tissue that is hypoperfused and is in danger of infarcting. Penumbra is the region that is potentially salvageable with early recanalization. Neuroimaging can provide excellent estimates of the core and penumbra in individual patients and help the clinicians to decide which stroke victim will benefit from thrombolysis.

The goals of neuroimaging in acute stroke ischemia are:

- a) To assess brain parenchyma
- b) To rule out hemorrhage and other stroke mimickers
- c) To assess the intra- and extracranial circulation in order to depict endovascular thrombi
- d) To assess the perfusion of the brain tissue, the size of the infarcted core, and the surrounding penumbra [81]

1. Non Contrast CT (NCCT)

The speed, widespread availability, low cost, and accuracy in detecting subarachnoid and intracranial hemorrhage have led conventional unenhanced computed tomography (NCCT) scanning to become the first-line diagnostic tool for the emergency evaluation of acute stroke.

CT findings that are useful in the detection of acute ischemia are focal parenchymal hypodensity, obscuration of the lenticular nuclei and the insular cortex, sulcal effacement due to brain edema, loss of gray-white matter differentiation, and the hyperdense MCA sign due to an acute thrombus in an intracranial vessel which has typically high attenuation [81, 87] (Figure 7).

Figure 7. Non-contrast CT of the brain with evidence of subarachnoid hemorrhage and interhemispheric hematoma.

2. CT Angiography (CTA)

CT angiography is the next step in assessing intracranial and extracranial circulation. It is a widely available, fast and simple technique that is capable of detecting endovascular thrombi. CT angiography is performed after intravenous injection of contrast agent and it visualises vessels from the aortic arch to the circle of Willis. Multiplanar reformatted images and maximum intensity projection images are produced at a three-dimensional display workstation [81] (Figure 8).

CTA can detect endovascular thrombi and can define the level of intracranial vascular occlusion in patients presenting within 6 hours of embolic stroke onset [87]. It can detect large vessel occlusion but it can also provide information about collateral flow and lesion extent. Plaque burden at the origins of internal carotid arteries and arterial dissection can also be detected by CTA [87]. CTA plays a major role in the exclusion of unnecessary thrombolysis in patients presenting with acute embolic stroke, but who don't have large vessel occlusions amenable to thrombolysis [87]. CT angiographic demonstration of a significant thrombus burden, can guide appropriate therapy in the form of intra-arterial or mechanical thrombolysis, as it is known that intra-arterial thrombolysis may be more efficacious than intravenous therapy in patients with acute stroke and a significant thrombus burden [81]. Unlike MRA, CTA is an anatomic imaging technique and therefore it is not likely to yield false-positive results for occlusion due to slow flow or artefact [87].

Figure 8. CT Angiography: a saccular aneurysm of the basilar tip is depicted.

3. CT Perfusion Imaging

CT perfusion imaging (CTP) in addition to CTA is fast, available and safe and adds no more than 10 minutes to the time required to perform a standard NCCT. CTP is based on dynamic i.v. administration of a contrast agent, which is tracked with serial imaging during its first pass circulation through the brain tissue capillary beds. Depending on the assumptions regarding the arterial inflow and venous outflow of the tracer, perfusion parameters can be estimated mathematically. CT perfusion maps then can be generated in a short time at an appropriate workstation.

CT perfusion imaging is used to estimate the following perfusion parameters:

- Cerebral blood volume (CBV), which is the volume of blood per unit of brain tissue (normal range, 4–5 mL/100g)
- Cerebral blood flow (CBF) defined as the volume of blood flow per unit of brain tissue per minute (normal range in gray matter, 50–60 mL/100 g/min)
- Mean transit time (MTT), defined as the time difference between the arterial inflow and venous outflow ($MTT = CBV/CBF$)
- Time to peak enhancement (TTP), which represents the time from the beginning of contrast material injection to the maximum concentration of contrast material within a region of interest (ROI) [81].

As mentioned before, the infarcted core is a region of brain tissue which is severely hypoperfused and irreversibly infarcted or is destined to infarct regardless of therapy. It is defined as an area with prolonged MTT, markedly decreased CBF and markedly reduced CBV.

The ischaemic penumbra, which in most cases surrounds the infarct core, also has prolonged MTT but in contrast has only moderately reduced CBF and importantly near normal or even increased CBV (due to autoregulatory vasodilatation) [83]. Hence, functional images can help differentiate between:

- A favourable pattern of ischemic stroke which consists of a small infarcted core and a large penumbra
- An unfavourable pattern with a large core and a small penumbra
- An intermediate pattern with relatively equal size of core and penumbra, and
- Malignant pattern with a very large core and small penumbra

This way the clinicians are guided in their decision-making process on whether to attempt revascularization or not [84].

4. MRI Imaging

Conventional MRI used in the evaluation of acute stroke, typically includes T1-weighted spin-echo, T2-weighted fast spin-echo, fluid-attenuated inversion recovery, T2*-weighted gradient-echo, and gadolinium-enhanced T1-weighted spin-echo sequences [81].

MRI can diagnose infarcts of all stages of evolution but it is most sensitive after the hyperacute stage. The basic findings during the hyperacute stage are loss of flow voids on T2-weighted images, FLAIR hyperintensity in the affected vessels and stasis of contrast material in the vessels of the affected territory [87]. Typical MR imaging findings in the acute phase include hyperintense signal in white matter on T2-weighted images and FLAIR images, with a resultant loss of grey-white matter differentiation. Sulcal effacement and mass effect can also be demonstrated. In the subacute phase, parenchymal swelling and enhancement after contrast administration may be seen [87].

T2*-weighted gradient-echo images and susceptibility-weighted imaging (SWI) depict an acute intracranial hemorrhage as an area of abnormal blooming. Compared with CT and other MR imaging methods, these techniques are superior in detecting very small cerebral hemorrhages in patients with acute stroke. However the impact of depicting these small hemorrhages in the infarcted area in deciding thrombolytic therapy is not strongly established yet [81, 92].

MR angiography (MRA) is divided into non-contrast (TOF MRA and Phase-contrast MRA) and contrast-enhanced techniques (Figure 9). TOF MRA is a gradient echo sequence that depicts vascular flow. Phase-contrast MRA is a gradient echo sequence that depicts blood flow by quantifying differences in the transverse magnetization between stationary and moving tissue. Contrast-enhanced MRA is usually obtained from the arch to the skull base. Three-dimensional TOF MRA is quite sensitive and specific for the evaluation of intracranial proximal stenoses and occlusions. Phase-contrast MRA can evaluate collateral flow patterns

in the circle of Willis. MR angiography is useful for detecting intravascular occlusion due to a thrombus and for evaluating the carotid bifurcation in patients with acute stroke. However MRA is relatively insensitive in depicting stenoses in distal intracranial vessels [87].

Figure 9. MR Angiography.

5. Diffusion Weighted Imaging

Diffusion weighted imaging (DWI) was introduced in the clinical setting in the mid-1990s and today is the most reliable method for detecting acute ischemia and it can be accomplished in less than 2 minutes [81]. The abnormal finding of infarction is an area of hyperintensity on DWI. This is likely caused by the cessation of ATP production and the dysfunction of $\text{Na}^+\text{-K}^+$ pump, which is unable to remove excess water from the cells, resulting in cytotoxic edema [88]. The actual diffusion coefficient cannot be measured by using diffusion-weighted MR imaging, for a number of reasons. Hence, the diffusion coefficient obtained from orthogonal diffusion-weighted MR images in all three planes is called the apparent diffusion coefficient (ADC) [81]. The ADC map is used to confirm that the signal abnormality on DWI is caused by restricted diffusion. Acute infarction is demonstrated as a hyperintense area on DWI and as an area of low signal intensity on ADC map and it corresponds to the irreversibly infarcted brain tissue. Diffusion restriction with reduced signal on ADC map has been observed as early as 30 minutes after the onset of ischemia. This information is critical as thrombolytic therapy can be started within the “golden period” of 3 hours from the onset of symptoms resulting in early reperfusion of the hypoperfused tissue. In the hyperacute stage of infarction (<6 hours) the DW signal intensity is increased with a corresponding low ADC. In the acute phase (6 hours to 3 days) there is a further increase of the DW signal of the infarcted tissue and also a lower ADC. In the subacute phase (3 days to 3 weeks), there is a pseudonormalisation of the ADC. This is likely due to the development of vasogenic edema along with the persistence of cytotoxic edema. In the chronic stage (3 weeks to 3 months) there is an increase in ADC with a bright signal on ADC map [88]. In contrast to unenhanced CT or conventional MR imaging, which have low sensitivities (50%) for acute

ischemia detection within the first 6 hours after onset of symptoms, diffusion-weighted imaging was reported to have had high sensitivity and specificity, of 88%-100% and 86%-100%, respectively, in various studies [81].

6. Perfusion-Weighted MR Imaging (PWI)

While diffusion-weighted MR imaging is most useful for detecting irreversibly infarcted tissue, perfusion-weighted imaging may be used to identify areas of reversible ischemia as well. Perfusion-weighted MR Imaging describes techniques that study perfusion by visually depicting hemodynamic conditions at the microvascular level. Perfusion-weighted imaging techniques rely on measurement of the concentration within each voxel of a contrast agent that is dissolved in the blood. Multiple echo-planar images are made with a high temporal resolution.

Various post-processing algorithms are used to convert the sequence of dynamically acquired images into synthetic maps that depict any of perfusion parameters for each brain voxel [87].

What is the clinical role of PWI in conjunction with DWI? In the acute stroke setting, a region that shows both diffusion and perfusion abnormalities is thought to represent irreversibly infarcted tissue, while a region that shows only perfusion abnormalities and has normal diffusion likely represents viable ischemic tissue, or a penumbra. These are very helpful information in order to decide thrombolytic therapy [81, 85].

7. CT versus MR Imaging in Acute Stroke Evaluation

CT is widely available, and a stroke imaging protocol that consists of unenhanced CT, CT angiography, and CT perfusion imaging can be executed in 5 minutes for the comprehensive evaluation of the extra- and intracranial circulation, the amount of infarcted brain tissue, and the penumbra. The MR imaging protocol for evaluation of stroke, which includes conventional MR imaging, diffusion-weighted imaging, MR angiography, and perfusion-weighted imaging, may take a little longer (15 minutes) [81]. NCCT is a widely available tool and a very reliable one in detecting acute hemorrhage. Until recently, it is considered to be superior than MRI in depicting hemorrhage, however recent studies have shown that MRI, including T2*-weighted gradient-echo images or susceptibility-weighted imaging, can also depict hyperacute haemorrhage [91-93]. These new techniques, as mentioned before, are superior to CT in depicting old hemorrhages and hemorrhagic transformation in the infarcted area [92]. DWI is definitely superior to CT in evaluating the irreversibly infarcted tissue even in the hyperacute phase [87, 88]. CTA may be superior to MRA in depicting vessel occlusion because MRA is vulnerable to motion artifacts. The two modalities including CTP and PWI are equally useful for evaluating acute stroke and provide equivalent depiction of the penumbra. Some authors have pointed out that whereas CT is simple to perform, MR findings are simple to interpret [81]. Disadvantages of CT are ionizing radiation and higher risk for anaphylaxis and toxic effects on kidneys because of the administration of iodinated contrast material. On the other hand MRI is not so widely available as CT, it cannot be performed in patients with pacemakers, aneurysm clips, or other

ferromagnetic materials in their bodies and it may not be easy to perform in patients who need life support equipment [82]. Acute stroke imaging protocols vary among institutions, depending on the availability of imaging time, software, and expertise.

8. Intracranial Hemorrhage (ICH)

All hemorrhages, according to WHO classification are divided into cerebral, subarachnoid, subdural and intraventricular [90].

a. Etiologies of Intracranial Hemorrhage

Hypertension, hemorrhagic transformation of a previous cerebral infarction and cerebral amyloid angiopathy, are the most frequent causes of intraparenchymal hemorrhage in patients older than 60 years. In younger patients, we have to consider as possible causes of intraparenchymal hemorrhage, underlying cerebrovascular malformations such as arteriovenous malformations and cavernous angiomas, vasculopathy and venous infarctions due to venous thrombosis. Cerebral hemorrhage can also occur at any age in the case of an underlying tumor. Hemorrhage may be the first manifestation of a previously unknown tumor. Bleeding diathesis, coagulopathy due to anticoagulants and thrombolytic drugs administration should also be taken into account. Usage of illicit drugs and alcohol, endocarditis, congenital heart defects and long operations on heart should also be considered as possible causes of cerebral hemorrhage. Other more rare causes include eclampsia, encephalitis and brain abscess, Moyamoya disease, vasculitis, and hereditary hemorrhagic telangiectasia [86, 90, 94].

Non-traumatic subarachnoid hemorrhage (SAH) is usually related to an aneurysmal rupture (in 75% of cases) or a vascular malformation [89].

Subdural and epidural hematomas are most frequently caused by trauma. When there is no history of previous trauma we have to think of AVM rupture, dural arteriovenous fistulas, or coagulopathy [90].

The most frequent non-traumatic reasons for intraventricular hemorrhage are hypertonic hemorrhage in the basal ganglia, AVM rupture and deep cavernoma.

Dural sinus and cerebral vein thrombosis can lead to venous infarctions. Common causes of venous thrombosis are dehydration, pregnancy, infection, oral contraceptives, coagulopathies, malignancies, collagen vascular diseases and trauma [86, 90]. Detection of hemorrhage and identification of the etiology of non-traumatic intracranial hemorrhage is the major task of every neuroimaging method and it is crucial for the patient's therapeutic management.

b. What Are the Imaging Recommendations for Detecting a Spontaneous Nontraumatic Intracranial Hemorrhage?

Radiologists and clinicians should always take into consideration the patient's clinical history and physical examination's findings in order to decide which imaging modalities are suitable for each patient.

Non-contrast computed tomography (NCCT) is, in most hospitals, the first imaging modality used to investigate primary intraparenchymal hemorrhage. CT scan is an excellent

tool for depicting acute hemorrhage. It can demonstrate the location and size of hemorrhage as well as the possible complications of it such as intraventricular hemorrhage, hydrocephalus, edema and herniations [82]. If the patient is old and suffers from hypertension and NCCT reveals an hematoma in the region of basal ganglia, which is typical for hypertensive intraparenchymal hemorrhage, there is no need for further radiological investigation. If there is no clear cause of hemorrhage or an atypical appearance on NCCT, MRI (including Diffusion-weighted imaging and T2*-weighted imaging or susceptibility-weighted imaging) should be performed [89].

T2*-weighted imaging or susceptibility-weighted imaging, are able to detect intracranial hemorrhage in the hyperacute stage and in chronic stage as well [91-93]. Multifocal black dots demonstrated on T2*-weighted imaging or susceptibility-weighted imaging, guide us to hypertensive or amyloid angiopathy [86, 90].

MRI with gadolinium administration contributes to investigate an underlying pathology such as tumors or vascular anomalies. CT angiography (CTA) and MR angiography (MRA) are the methods of choice for investigation of vascular anomalies such as aneurysms or AVMs, while CT venography (CTV) and MR venography (MRV) can reveal dural sinus and cerebral vein thrombosis. If the cause of intracerebral hemorrhage remains unclear we have to proceed to DSA. MRI can be used for the follow up [89].

c. What Is the Best Imaging Modality in Order to Investigate Spontaneous Intracranial Hemorrhage. CT or MRI?

Non-contrast computed tomography (NCCT) is in most hospitals the first imaging modality used to detect ICH. It is widely available, fast and can be performed in patients who are unable to tolerate an MRI examination or who have contraindications to MRI such as pacemakers, aneurysm clips, or other ferromagnetic materials in their bodies [82]. In addition, CT scan is more accessible to patients who need special equipment for life support. CT scan, as mentioned before, is an excellent tool for depicting acute hemorrhage and its potential complications. Contrast-enhanced CT scanning can be used easily for patients at risk for hematoma expansion [82]. NCCT in combination with contrast enhanced CT (CECT), CTA and CTV can reveal underlying abnormalities such as aneurysms, arteriovenous malformations, pre-existing tumors. However NCCT is less sensitive than MRI in depicting and visualizing ischemic changes in a very early stage, or small infarcts especially situated in the brainstem or posterior cranial fossa. Patient's exposure to ionizing radiation and possible allergic reactions to the iodinated contrast medium are also disadvantages of CT [81].

On the other hand, MRI is much more sensitive than CT in depicting ischemic changes in a very early stage. Diffusion-weighted imaging (DWI) is able to detect ischemic changes 30 minutes after vessel occlusion [81]. The usage of DWI and perfusion weighted imaging (PWI) can also detect the extent of the infarcted core and the penumbra. These are very significant elements for the decision of management and use of thrombolysis. In the past, MRI has been considered unable to detect hemorrhage in the hyperacute stage. In recent years there have been studies that support that MRI, including T2*-weighted imaging or susceptibility-weighted imaging, can be very sensitive in the detection of hyperacute cerebral hemorrhage [91, 93].

Some authors also noticed that MRI was more sensitive than CT in depicting hemorrhagic transformation of an ischemic infarction, which may play a role in deciding

thrombolytic therapy [81, 92]. MRI is also much more sensitive than CT in detecting hemorrhages in chronic phases and old microbleeds, which also contributes to the diagnosis and therapeutic management [92]. However, MRI is less sensitive than CT to differentiate small acute hemorrhages from chronic ones, because small acute hemorrhages, with minimal or no edema, may have similar characteristics to calcifications or endovascular clot [92]. MRI with gadolinium administration, MRA and MRV can help visualize the possible cause of cerebral hemorrhage. Some authors support that routine multimodal MRI adds diagnostic yield to NCCT and helps changing the therapeutic management [94]. Others have decided to examine patients with suspected cerebral ischemia only with MRI in order to save time and if there is no hemorrhage demonstrated on MRI, thrombolysis may be started [96]. However MRI is not so widely available as CT, some hospitals are supplied with low field strength equipment, with which the modern sequences cannot be performed and MRI is sometimes difficult to perform in critically ill patients who need life support equipment.

d. Radiological Findings of ICH on CT and MRI

Based on time, all hemorrhages can be divided in 5 stages, the hyperacute (the first 24 hours), the acute (1-3 days), the early subacute (3-7 days), the late subacute (7-14 days), and the chronic stage (later than 14 days) [95].

Figure 10. Brain CT showing a mesencephalic hematoma.

The acute extravasated blood is hyperdense on CT scans. The hematoma's density in the first few hours can reach 60-80 HU [90]. On MRI, hyperacute hemorrhage containing oxyhemoglobin, appears to be made of three parts: a center, a periphery and a surrounding rim. The center is slightly hypointense or isointense relative to the brain on T1-weighted images. On T2-weighted images the center is heterogeneous and slightly hyperintense relative

to the brain. The periphery of the hematoma appears hypointense and the surrounding rim, which corresponds to perilesional edema, appears hyperintense. On T2*-weighted imaging or susceptibility-weighted imaging, the center appears heterogeneous iso- or hyperintense, but the periphery appears hypointense. As time passes there is progressive enlargement of the periphery of the lesion towards the center [93]. Such lesions do not enhance after the administration of a gadolinium-based contrast agent.

During the acute stage, hematoma continues to appear hyperdense on CT (Figure 10). On MRI, the hematoma appears iso- to hypointense on T1 weighted images, markedly hypointense on T2 weighted images due to the formation of deoxyhemoglobin [89, 95]. In this phase perilesional edema increases [90].

In the subacute phase there is a progressive decrease in hematoma's density on CT. In the early subacute stage, hematoma appears hyperintense on T1 weighted images and hypointense on T2 weighted images due to the existence of intracellular methemoglobin [89, 90]. In the late subacute stage, the hematoma appears hyperintense on both T1 and T2 weighted images due to extracellular methemoglobin [89, 90].

In the chronic stage, at last, hematoma appears as a hypodense area on CT with density close to CSF. It may also appear as a slit-like lesion or calcinated areas [89, 90]. On MRI hematoma appears hypointense on both T1 and T2 weighted images because of the existence of hemosiderin and extracellular ferritin. In the subacute and chronic stage peripheral rim enhancement may be noticed after contrast administration either on CT and MRI [89, 95].

e. Radiological Appearances of Specific Causes of ICH

Hypertensive Hemorrhage

Hypertensive hemorrhage is the most common cause of intracranial hemorrhage and it most commonly involves the lenticulostriate arterial branches of the middle cerebral artery, leading to putaminal or caudate hemorrhage. It may also result from rupture of the small perforating branches, in which case it leads to pontine or thalamic bleeds. Large hematomas often dissect into the ventricles, causing intraventricular extension [95].

Hemorrhagic Transformation of Cerebral Infarction

Infarcted brain tissue has a propensity to bleed, particularly when reperfused in the acute phase. Infarcted brain tissue can be recognized on MRI and especially Diffusion -weighted images. Hemorrhagic transformation in the infarcted area can be demonstrated on T2*-weighted imaging or susceptibility-weighted imaging. However, early massive bleeding may obscure the underlying infarct. The risk of bleeding in venous infarction is higher than arterial infarction [95].

Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA), is caused by the deposition of beta-amyloid in the arterial media and/or adventitia of small arteries and arterioles in the meninges, cortex, and cerebellum [95]. Unlike the hemorrhages due to hypertension, which are usually located in the basal ganglia, the presense of multiple and small hemorrhages in the cortex and subcortical white matter of cerebral hemispheres, and rarely in the cerebellum, is typical for amyloid angiopathy [90]. MRI is the best imaging tool to depict old bleeds on T2*-weighted imaging or susceptibility-weighted imaging [92].

Intratumoral Hemorrhage

There is an increased risk for hemorrhage in brain tumors with significant neovascularity. High-grade tumors, such as glioblastoma multiforme, and certain metastases (e.g., melanoma, renal cell carcinoma, thyroid carcinoma, choriocarcinoma, lung cancer) are more likely to bleed than others. In the case of an intratumoral hemorrhage, blood of different ages may be present and admixed with abnormal neoplastic tissue. That explains why MRI appearances are often atypical and complex. There is usually delay of the evolution of changes in MRI signal intensity of hemorrhage inside the tumor. Vasogenic edema is greater with brain tumors than with primary ICH. The edema surrounding a primary ICH usually resolves after 4-8 weeks, while edema due to intratumoral hemorrhage persists even into the chronic phase of hematoma. Administration of contrast medium may reveal tumor enhancement [95].

Cerebrovascular Malformations (CVMs)

Cerebrovascular malformations are a heterogeneous group of disorders that represent lesions affecting arteries, veins, capillaries or various types of vessels. Arteriovenous malformations (AVMs) and cavernous malformations, may hemorrhage abruptly without any warning sign. Developmental venous anomalies and capillary telangiectasias are generally benign lesions and clinically silent [89]. MRI with gadolinium administration, including T2*-weighted imaging or susceptibility-weighted imaging and MRA, can reveal cerebrovascular malformations.

Catheter angiography is often needed to further evaluate AVMs and arteriovenous dural fistulae. On MRI, AVM appears as a tightly packed honeycomb of flow voids like a “bag of worms” caused by high-velocity signal loss. Areas of hemorrhages in different stages can be seen [89].

Arteriovenous dural fistulae are a network of tiny vessels in the wall of a thrombosed dural venous sinus [89].

Cavernous hemangiomas have a typical popcorn-like appearance with locules of variable size containing blood products of different ages [89]. Multiple lesions at different locations are seen in 50% of patients with cavernous hemangiomas [95].

Developmental venous anomalies, formerly known as venous angiomas, appear like an umbrella collection of enlarged medullary veins (Medusa head) [89].

Non-Traumatic Subarachnoid Hemorrhage (SAH)

Nontraumatic subarachnoid hemorrhage (SAH) accounts for 5% of all acute strokes. As mentioned before, the most common cause of SAH is a ruptured intracranial saccular (berry) aneurysm (aSAH). Saccular aneurysms are focal sac or berry like arterial dilatations. They are most commonly located on the circle of Willis and the middle cerebral artery bi- or trifurcation. That is the reason why most aSAHs are located in the suprasellar cistern and the sylvian fissure. Other types of aneurysms are pseudoaneurysms, blood blister-like aneurysms and fusiform aneurysms [89]. The imaging modality recommended for investigating SAH is NCCT, which can demonstrate blood as hyperdense material in the sulci and cisterns. CTA with multiplanar reformation can be the next step as it can depict an aneurysm in 90-95% of cases, if the aneurysm is larger than 2mm [89]. If CTA is negative, we can proceed to DSA (Figure 11). On MRI, SAH may be demonstrated as high signal intensity material in sulci, compared with normally hypointense CSF spaces on Fluid-Attenuated Inversion Recovery (FLAIR) images. FLAIR MRI is similar to CT in terms of its findings in SAH [95]. It can be

more sensitive than CT in detection of small SAH but it is less specific as infectious material in the CSF spaces can present with the same signal intensity [89]. T2*-weighted images can potentially demonstrate SAH as an area of low signal intensity in normally hyperintense subarachnoid spaces. On T1-weighted images, acute SAH may appear as intermediate or high signal intensity in the subarachnoid space [95] and subacute SAH may appear as high signal intensity in CSF spaces [90]. Magnetic resonance angiography (MRA) may be useful in the evaluation of aneurysms and other vascular lesions that cause SAH. Factors that limit the utility of MRA in the diagnosis of acute SAH are its low sensitivity for aneurysms less than 5 mm, its inability to depict small aneurysm contour irregularities, and its difficulty in providing high-quality images in patients who are agitated or confused [95].

Figure 11. Digital Subtraction Angiography (DSA). A large saccular aneurysm of the left ICA bifurcation is shown.

Venous Infarction

Venous infarction can be a challenging diagnosis and it is caused by cerebral venous thrombosis, complicating both dural sinus thrombosis and deep cerebral vein thrombosis. Several conditions can lead to venous thrombosis, as mentioned before, like acute dehydration, hypercoagulable states, infection and malignancy [86]. The imaging modalities recommended are NCCT where thrombosed sinuses and cortical veins appear hyperdense and cortical/subcortical hemorrhages and edema can be demonstrated. The next step can be CECT. Empty delta sign is produced by enhancing the dura that surrounds the non-enhancing thrombus in a thrombosed sinus. CTV can demonstrate the thrombus as a filling defect in the sinus. If the CT exams are negative and there is a high clinical suspicion of venous thrombosis we can proceed to MRI including T2*-weighted imaging or susceptibility-weighted imaging and MRV (Figure 12) with gadolinium administration, in order to visualise

the thrombus [89]. MRI is superior to CT in detecting the complications of sinus thrombosis. Edema is easier to be detected on T2-weighted images and FLAIR images, while infarcted areas are best demonstrated on DWI. Hemorrhage may be detected on CT and MRI as well.

Chapter 85

THE ROLE OF IMAGING IN PARATHYROID SURGERY

***I. Koutelidakis*, A. Doundis, A. Ananiadis, S. Kalaitzis,
T. Kaltsikis and V. Papaziogas***

2nd Department of Surgery, Medical School,
Aristoteleio University of Thessaloniki, Greece

ABSTRACT

Primary hyperthyroidism (PHPT) is mainly caused by a parathyroid adenoma. The localization of this parathyroid lesion is essential for the surgical treatment of the disease. Various invasive and non-invasive localizing tests are available for evaluating PHPT. The traditional non-invasive imaging modalities include ultrasonography, scintigraphy, computed tomography and magnetic resonance imaging. In the era of minimally invasive parathyroidectomy (MIP), the utilization of SPECT and SPECT/CT in radioimaging, the 4D CT and various combinations of individual visualization techniques have established parathyroid imaging as an essential supplement to parathyroid surgery.

INTRODUCTION

There are typically two superior and two inferior parathyroid glands (PG) in humans. The superior PG develops from the dorsal wing of the third pharyngeal pouch and the inferior of the fourth. PG are composed mainly of chief cells, oxyphil cells and adipose tissue. The normal weight of each PG is about 40 to 50mg and measuring about $5 \times 3 \times 1$ mm. The inferior thyroid artery is the predominant vascular supply to both superior and inferior PG in the majority of the cases [1].

The PG are located in the posterior surface, adjacent to the poles of the lobes of the thyroid gland. A nomenclature of possible locations of the PG is shown in figure 1 [2]. It should be mentioned that the inferior PG are consistently anterior (ventral) to the recurrent laryngeal nerve (RLN) and the superior PG posterior (dorsal) to the RLN [3].

* Corresponding Author's Email: iokoutel@gmail.com.

In approximately 10% of patients supernumerary glands and less than four glands have been reported. When the PG are situated above or below the level of the thyroid gland or they are distant from its posterior aspect, they are considered ectopic. Ectopic PG are usually intrathyroidal, in the carotid sheath, the tracheoesophageal groove or in the thymus or the superior mediastinum [4].

Figure 1. (a) Anterior view displaying nomenclature of possible locations of parathyroid adenomas. A: Superior gland, in proximity of posterior surface of thyroid parenchyma, may be intracapsular/compressed. B: Superior gland, fallen posteriorly into tracheoesophageal groove, no contact with posterior surface of thyroid tissue in the cranio-caudal confines of thyroid lobe. C: Superior gland, fallen posteriorly into tracheoesophageal groove, no contact with posterior surface of thyroid tissue and is caudal/inferior to cranio-caudal confines of thyroid lobe. D: Superior or inferior gland, in mid region of posterior surface of thyroid parenchyma near junction of RLN and inferior thyroidal artery. E: Inferior gland, in region inferior to thyroid parenchyma, anterior to trachea. F: Inferior gland, descended into thyrothymic ligament or superior thymus and may appear in mediastinum. G: Intrathyroidal parathyroid. (b) Lateral view [2].

PG secrete parathyroid hormone (PTH) which is the key regulator of calcium homeostasis. Hyperfunction of the PG is leading to a condition known as primary hyperparathyroidism (PHPT). Secondary hyperparathyroidism is commonly due to chronic kidney disease, in which low serum calcium concentrations stimulate diffuse gland hyperplasia, In those patients PT glands may continue to grow and become overactive, resulting in typical asymmetric hypertrophy because of autonomous function (tertiary hyperparathyroidism) [5]. Most cases of PHPT are caused by a single parathyroid adenoma

(90%). Other causes include hyperplasia of all four glands (5%), double adenomas (5%), and, rarely, parathyroid carcinoma. There is an increased incidence of parathyroid hyperplasia in multiple endocrine neoplasia type I. Another rare cause of PHPT is familial hypocalciuric hypercalcemia [6].

PHPT is a common disease occurring in about 1% of the adults. It is 2-3 times more common in women than men and peaks around the fifth decade of life. Diagnosis of PHPT is accomplished by biochemical findings. The most common presenting symptoms of PHPT include fatigue, hypertension, bone pain, muscle weakness, and psychiatric illness. All symptomatic patients and asymptomatic patients younger than 50 years, as well as patients meeting specific criteria are candidates for surgical therapy [7].

The traditional approach to parathyroid surgery consists of bilateral neck exploration in order to identify and visually inspect all four parathyroid glands. The success of this approach exceeds to 90-95%. However, cervical exploration requires a larger incision, longer operating time and can have higher morbidity [1].

With the progress in parathyroid imaging a minimally invasive approach can be accomplished. The minimally invasive parathyroidectomy (MIP) includes small incision, outpatient parathyroidectomy, endoscopic or video assisted surgery and operation under local anesthesia. MIP is associated with significant reductions in operative time and hospital stay, provides a better cosmetic result while decreasing the potential complications of bilateral exploration [8].

Various invasive and non-invasive localizing tests are available for evaluating PHPT. The traditional non-invasive imaging modalities include ultrasonography, scintigraphy, computed tomography and magnetic resonance imaging.

In the era of MIP, the utilization of SPECT and SPECT/CT in radioimaging, the 4D CT and various combinations of individual visualization techniques have established parathyroid imaging as an essential supplement to parathyroid surgery.

ULTRASONOGRAPHY

Ultrasonography of the neck (US) is the most generally available and cheap examination in parathyroid imaging.

With the use of high-frequency 12- or 15-MHz transducers and the patient in supine position with his or her neck hyperextended, the neck is examined from the carotid bifurcation superiorly to the sternal notch inferiorly and the carotid artery/internal jugular vein laterally [9].

Normal PG are rarely visualized by US, because of their small size and insufficient acoustic difference compared to adjacent thyroid tissue. However, parathyroid adenomas, hyperplasia, and carcinomas exhibit a relatively hypoechogenic pattern, due to their compact cellularity relative to thyroid tissue [10].

Parathyroid adenomas are usually well-circumscribed ovoid, longitudinal in shape and tend to be solid and homogeneously hypoechoic relative to echogenic thyroid tissue. An echogenic line that separates the thyroid gland from the enlarged parathyroid gland can usually be seen. Larger adenomas are more likely to have cystic change, lobulations, increased echogenicity due to fatty deposition, and occasional calcifications [11]. (Figure 2).

Figure 2. Hypoechoic left lower pole (A) and behind the left lower pole (B) parathyroid adenomas identified by ultrasound [1].

Figure 3. 44-year-old woman with hyperparathyroidism due to right inferior parathyroid adenoma. Resected gland weighed 629 mg, nearly 15 times weight of a normal gland (40–50 mg). A, Sonogram shows typical hypoechoic adenoma (arrows) deep in relation to lower pole of thyroid. B, Color Doppler sonogram shows peripheral feeding vessel (arrow) characteristic of parathyroid adenomas. Also note typical arc or rim vascularity [21].

Color Doppler US (CDUS) has also been used to localize enlarged parathyroid glands, while Contrast-Enhanced US (CEUS) has not yet shown a potential benefit. In CDUS, parathyroid adenomas tend to be hypervascular lesions. An extrathyroidal artery may lead to a parathyroid adenoma in the majority of patients. An extrathyroidal feeding vessel may provide a roadmap to an otherwise inconspicuous gland. Characteristically, the extrathyroidal artery enters at one pole of the gland (polar artery). However, color Doppler sonograms of parathyroid adenomas may not show increased vascularity until the lesions are 1 cm in size [12]. (Figure 3).

The sensitivity of US for detecting enlarged parathyroid glands ranges from 70% to 100% as it is, to a great degree, depended to the experience of the examiner, the size of the

PG lesion and the pathology of the adjacent thyroid tissue. An advantage of US is the fact that the identified concurrent thyroid disease can be addressed by fine needle aspiration (FNA) preoperatively or intraoperatively.

Additionally, even when US findings are atypical, US can be helpful leading to further investigation [10, 13-14].

False positive or negative sonographic diagnosis may be due to thyroid nodules, prominent blood vessels, cervical lymph nodes, esophagus and longus colli muscle and poor visualization of neck structures due to previous surgery. It must be stressed that US does not enable localisation of parathyroid glands placed in the mediastinum or in retrotracheal or retroesophageal regions due to acoustic shadows from bones or air spaces [15].

RADIOIMAGING

The use of radionucleotid agents (radioimaging) is the most widely adopted method in parathyroid imaging.

Among several radiotracers that have been used in the past or are still in use, Hexakis-2-methoxy-isobutyl-isonitrile labeled with technetium- 99m (99mTc-sestamibi) holds a predominant place.

99mTc-sestamibi consists of monovalent cationic lipophilic molecules which after intravenous (i.v.) injection distribute according to blood flow. These molecules cross the cell membranes according to the electrochemical gradient and intracellularly accumulate in the mitochondria of the oxyphil cells. 99mTc-sestamibi is also taken up by the thyroid gland, but it washes out more rapidly from normal thyroid tissue than out of PT glands. 99mTc-sestamibi is sequestered also in the myocardium, the salivary glands and in brown fat, which often is noted as a mild supraclavicular shade [16].

Two different protocols can be used in 99mTc sintigraphy.

The dual-phase protocol uses 99mTc-sestamibi alone. Early (10–30 min after injection) and delayed (1.5–2.5 h after injection) high-count images are obtained of the neck and chest. The concept of this technique is based on the different washout of the radiofactor between the thyroid and the abnormal parathyroid gland. Dual-phase imaging with 99mTc-tetrofosmin appears not to be useful because of rapid washout from parathyroid tissue. It should be mentioned that it is mainly a functional technique as it visualizes the difference in the wash out of the radiofactor between the thyroid and the parathyroid gland [17]. (Figure 4).

The dual-tracer protocol uses the coadministration of 99mTc-sestamibi as a substitute to Tl-201, 123I- or 99mTc pertechnetate. The thyroid images generated are then digitally subtracted from the 99mTc-sestamibi image and the residual signal after subtraction of the thyroid image is indicative of parathyroid uptake [17]. (Figure 5).

Two-dimensional planar PG scanning has been the standard technique for many years, the three-dimensional single photon emission tomography (SPET) was added later on and more recently the latter is combined with computed tomography (SPET/CT) leading to higher sensitivity rates [16]. (Figure 6).

Figure 4. Double phase ^{99m}Tc -sestamibi (^{99m}Tc -MIBI) parathyroid scintigraphy. In delayed imaging focal tracer retention is seen in the lower part of the thyroid gland (arrow). In the right and left anterior oblique views (RAO and LAO, respectively) the abnormal focus “changes its position significantly” relative to the submandibular salivary glands, indicating that it is located in the thyroid area and not deep in the neck [16].

Figure 5. In a patient with primary hyperthyroidism double tracer parathyroid scintigraphy shows a solitary focus adjacent to the lower pole of the right thyroid lobe which takes up ^{99m}Tc -sestamibi but not $^{99m}\text{TcO}_4^-$. It is very likely that this patient suffers from a single adenoma and he is suitable for a targeted surgical treatment [16].

If a dual-phase study is performed, then a high-resolution parallel-hole collimator or a pinhole or converging collimator can be used. Pinhole collimators are preferred if SPECT or SPECT/CT is not part of the imaging protocol. The range of intravenously administered radioactivity in adults is 740–1,110 MBq (20–30 mCi) [17].

In the double tracer subtraction technique the patient should remain immobile between the two successive scans and images should be carefully subtracted to avoid artifacts. In scanning in secondary HPT it is advised to withhold drugs refraining PG hyperfunction, namely calcimimetics for 2 weeks and vitamin D supplements for 1-4 weeks. If a subtraction technique is used, iodine-containing preparations should be avoided for >4 weeks and thyroxine for 3 weeks. If ^{123}I is used for thyroid scanning, thyrostatic drugs should be stopped for 1 week [18].

Figure 6. SPECT/CT demonstrating a right side parathyroid adenoma [1].

Sensitivity of $^{99\text{m}}\text{Tc}$ -sestamibi scintigraphy is reported to be about 80-100%.

Regional perfusion, gland size and functional activity, cell cycle phase, and prevalence of mitochondria-rich cells are some of the factors affecting the diagnostic accuracy of the method [19].

One further advantage of radioimaging is that the use of gamma probe intraoperatively can assist to the localization of the PG lesion and navigate the surgeon through challenging anatomies, especially in cases of ectopic PG [20].

COMPUTED TOMOGRAPHY

Computed tomography (CT) scanning was considered to be an effective adjunct to the conventional first line imaging techniques (US and radioimaging), reserved for cases of recurrent PHPT or cases of altered anatomy [21].

With the induction of 4D CT, therefore the addition of changes in the perfusion of contrast over time to the three dimensional anatomic CT images allowed for further functional information to the anatomic images due to the rapid uptake and washout of the contrast from the hyperfunctioning gland to the anatomic data and improved the sensitivity of the method [22,23].

Furthermore, 4D CT can be combined with US and this combination technique appears to be an excellent and cost effective preoperative localizing method for hyper-functioning parathyroid glands [24].

CT acquisition involves intravenous administration of nonionic iodinated contrast at a dose of 2 mL per kg patient weight. This technique relies on the vascularity of the parathyroid glands and their relative enhancement with contrast compared to the surrounding structures. A prominent feeding artery at the margin of a parathyroid adenoma (polar vessel), first described on ultrasound, may be seen in up to two thirds of parathyroid adenomas on high-quality 4D-CT studies. This finding can increase diagnostic confidence that a suspicious lesion is a parathyroid adenoma instead of a lymph node or thyroid nodule [25]. (Figure 7 and 8).

Figure 7. Computed tomography demonstrating a left sided parathyroid adenoma [1].

A 3-phase 4D-CT protocol with helical acquisition at 1.25-mm slice thickness from the bottom of the mandibular teeth down to the carina with noncontrast, early postcontrast, and delayed postcontrast imaging. The first noncontrast images can be helpful to distinguish adenomas from the intrinsically dense iodine-rich thyroid gland, while the early and delayed postcontrast imaging highlight the hypervascular nature of adenomas and their characteristic early washout [26].

Figure 8. Axial noncontrast (A), axial early phase postcontrast (B), and axial delayed phase postcontrast (C) images show a hypoattenuated hypodense nodule contiguous with the left posterior thyroid gland, which demonstrates avid early contrast enhancement and washout. Pathology revealed a 600-mg parathyroid adenoma [23].

Most modern multiphase 4D-CT techniques report a sensitivity and specificity exceeding 90%. In a CT picture, a parathyroid adenoma can be difficult to differentiate from lymph nodes, normal vessel structures or an exophytic thyroid tuberculum, particularly in patients who have previously undergone an operation within the neck. PG can be difficult to identify by CT at the area of the sternal notch and mediastinum due to streak artifact or being mistaken with lymph nodes. CT is also not particularly useful in identifying the parathyroid glands in patients who are not able to receive IV contrast [22].

MAGNETIC RESONANCE IMAGING

Magnetic Resonance Imaging (MRI) is an expensive and not always available technique; therefore, like CT scanning, MRI is reserved for cases of recurrent PHPT and ectopic PG lesions, despite the advantage of lack of ionizing radiation.

Figure 9. MRI demonstrating a left parathyroid adenoma [1].

Normal parathyroid glands usually are not seen on MRI. Parathyroid adenomas are isointense relative to the surrounding muscle and have low intensity on T1 weighted images.

They are generally hyper intense on T2 weighted images; however, hyper-functioning parathyroid glands show intense contrast enhancement on T1 weighted images [27]. (Figure 9).

The sensitivity of MRI in detecting abnormal parathyroid glands is reported from 70% to 90%. Factors resulting in false positive disease are concomitant thyroid disease and enlarged cervical lymph nodes that may mimic parathyroid adenomas. MRI is less sensitive and specific in identifying hyperplastic glands compared to parathyroid adenomas [28].

POSITRON EMISSION TOMOGRAPHY

Positron Emission Tomography/ Computed Tomography (PET/CT) with 18F-Fluorodeoxyglucose (18F-FDG) as an imaging tool in parathyroid cancer is not clearly reported in the literature, although there is a potential role of PET/CT in assessing the extent of disease and response to treatment which are the general principles used to correctly evaluate disease status. It has been proposed that FDG-PET can provided additional information related to the location and extent of parathyroid carcinoma, compared to CT, MRI and 99mTc-sestamibi [29,30]. (Figure 10).

Figure 10. Staging. Right: At Maximum intensity projection the parathyroid and pleural involvements are visible; Central and left: High 18F-Fluorodeoxyglucose-uptake is clearly displayed corresponding to the left parathyroid gland and right pleura in coronal, transverse and sagittal planes [30].

INVASIVE METHODS

The invasive methods used for diagnosing primary hyperparathyroidism are quite sensitive. Selective angiography shows 60% sensitivity, and intra-operative determination of parathormone in venous blood 80%. If both examinations are used, the sensitivity will increase to as much as 91–95%. These examinations help to accurately localize an adenoma (angiography) and to identify further adenomas or hyperplasia (PTH in venous blood) . Unfortunately, the methods may involve dangerous complications, including neurological disorders, embolism or renal failure [31].

CONCLUSION

The role of imaging in parathyroid surgery is more than crucial as it is the factor that can alter the operative strategy and offer to the surgeon the ability for more precise, focused and minimally invasive techniques.

With US and 99mTc sestamibi sintigraphy SPECT or SPECT/CT as first line examinations and the implication of 4D CT and MRI for selected cases, the majority of PG lesions can be precisely visualized and surgically removed.

The combination of different methods has been showed to increase the sensitivity of parathyroid imaging and the intraoperative measurement of PTH can provide confidence to the surgeon and lead to safer parathyroid surgery for the patient.

ABSTRACT

The adrenal glands constitute an indispensable part of human physiology and the diseases affecting them, ranging from benign to malignant ones, are often a challenge for the medical and surgical team. As a result, knowledge of the latest imaging technology is critical for the diagnosis and management of these diseases, in order to provide our patients with the best possible care. This chapter will present the various imaging modalities used for the adrenal glands, as well as discuss the advantages and disadvantages of each, in order to provide our readers with a practical decision-making guide.

INTRODUCTION

The adrenal glands constitute indispensable components of normal physiology. In terms of fundamental anatomy, the adrenal is divided in an outer layer, known as the cortex and in an inner layer, the medulla. [1-2] Each gland weighs approximately 2-4 grams. [1-2] Being of significant interest in surgical practice, their blood supply can arise from several different vessels including the aorta, the celiac trunk, the inferior phrenic or the renal arteries. [1-2] The adrenal cortex secretes glucocorticoids, mineralocorticoids and sex hormones, while the adrenal medulla secretes catecholamines (epinephrine and norepinephrine and dopamine). [3] From an embryology perspective, the adrenal cortex tissue stems from the intermediate mesoderm, whilst the medulla is derived from neural crest cells through a complex migration

* Corresponding Author's Email: sapalidis@med.auth.gr.

process. [4-5] Indeed, understanding the basis of embryonic adrenal development is a key aspect of deciphering certain pathology of this gland.

To begin with, lesions affecting the adrenal cortex have a higher prevalence than lesions located in the gland's medulla. [6] Further classification is focused on determining whether the lesion is primary or metastatic. Notably, primary adrenal lesions are metabolically functional in several cases leading to the clinical manifestations of hormone excess (e.g. Cushing syndrome, Conn syndrome, pheochromocytoma etc.). This is rare with metastatic adrenal tumors. [7] In respect with *lege artis* medicine, Radiologic Imaging proves to be indispensable in diagnosis and staging. Predominantly, adrenal imaging can be accomplished with Computed Tomography (CT), Magnetic Resonance Imaging (MRI), Ultrasonography (US), nuclear imaging and angiography which are implemented with regard to current guidelines and the surgical team's judgment [8].

METHODOLOGY

This chapter was composed after consulting with the PRISMA Statement (2009) [9]. A review of literature was conducted using PubMed (Medline). Inclusion criteria were: papers published in English which reported on humans. Both primary research (case reports, case series, clinical trials etc.) and secondary research (reviews and meta-analyses) were deemed eligible. Exclusion criteria were: papers published in a language other than English, experimental studies on animals, Editorials and commentaries or letters to the editor. Pre-decided keywords were applied to search the database and include the following: *adrenal lesion imaging, adrenal lesion CT, adrenal lesion MRI, adrenal lesion US, adrenal lesion nuclear imaging, adrenal lesion angiography, laparoscopic adrenalectomy, robotic adrenalectomy*.

MINIMALLY INVASIVE ADRENALECTOMY: NOVEL DIRECTIONS AND LIMITATIONS

1. The Role of Laparoscopy in Adrenal Surgery

Gagner introduced laparoscopy in the field of adrenal surgery in 1992. [10] Indisputably, in the 21st century, laparoscopic adrenalectomy has prevailed over conventional open surgery as the gold standard of care, mainly due to diminished ICU and hospital stay, fewer post-operative complications and higher cosmetic satisfaction expressed by patients. The fact that the adrenals are located in the retroperitoneal space ignited the genesis of several approaches such as: the lateral retroperitoneal, the transperitoneal, the posterior retroperitoneal and even the transthoracic technique [11].

Lateral Retroperitoneal Approach

The patient is subjected to general anaesthesia and placed in the lateral decubitus position. The ipsilateral, to the affected side, arm is suspended approximately 60°, whilst the contralateral arm safely rests on a special board protected with padding. Moreover, under the

contralateral axilla a soft cushion is applied. [11-12] Left adrenalectomies usually require four trocar portals. On the other hand, it is typical to utilize 5 portals when performing right adrenalectomies. [11-12] Trocars are inserted transversally along the posterior auxiliary and mid-clavicular line (just below the rib cage). During left adrenalectomy special care must be given out to the splenic flexure, the spleen and the tail of the pancreas. When working in close approximation to the right colonic flexure, the surgeon must be cautious in order to avoid inflicting injury to right lobe of the liver. Indeed, identification and clipping of the adrenal vein constitute priorities of paramount significance.

Transperitoneal Approach

This technique bears a most distinctive advantage. The surgeon has optimal visualization of the abdomen, which effectively decreases technical difficulties and leads to improved post-operative outcomes. [13] The transperitoneal approach constitutes a wise choice for pheochromocytomas and malignant tumours.

Posterior Retroperitoneal Approach

Walz et al introduced this approach in which the adrenal is resected from the superior pole of the kidney prior to adrenal vessel ligation. [14-15] Even though this technique has been questioned [11], Cleveland clinic series [16] and systematic reviews have revealed that the posterior retroperitoneal is similar in outcomes with the lateral retroperitoneal approach if not superior.[17] Limitations exist though, as these results can only be regenerated when the procedure is performed by experienced surgeons in carefully selected groups of patients.

Transthoracic Approach

This technique was initially described in 2001. Four ports were utilized without pneumo-insufflation. The diaphragm was incised under ultrasound guidance and the adrenal was visualized in the retroperitoneal space. Ultimately vessel ligation and specimen resection was successful. Gill et al. conclude that this approach is oriented towards patients with significant abdominal and retroperitoneal fibrosis from previous surgeries [18].

Indications and Contraindications to Laparoscopic Adrenalectomy

The usual scenario involves a benign, solitary, adrenal lesion with either cortical or medullary location. Specifically, non-secreting cortical adenomas represent the vast majority of cases, with secreting adenomas (e.g., aldosteronomas, glucocorticoid secreting tumors), pheochromocytomas and metastases accounting for just a minor percentage of the total number of adrenal lesions. Other rare lesions regard neuroblastomas, myelolipomas, sex-hormone secreting tumors, ganglioneuromas and adrenal cysts. [19] As far as contraindications are concerned there is no widely-accepted consensus amongst Endocrine Surgeons. However, open adrenalectomy is preferable to the laparoscopic procedure in cases involving lesions larger than 8cm or malignant adrenal tumours; especially in the event of infiltration of adjacent structures [11], [17].

Chai et al. highlight that size criteria were less restrictive with laparoscopic lateral transperitoneal adrenalectomy. [17] Notably, a solitary metastatic adrenal lesion does not constitute an absolute contraindication for laparoscopic adrenalectomy [11].

2. The Role of Robotics in Adrenal Surgery

The first series of robotic adrenalectomy were described in 1999 by Piazza et al. and Hubbens et al. [20-21] The Da Vinci ® system is superior to its predecessor (AESOP 2000 ®) on account of the EndoWrist technique and the three-dimensional vision. [23] A 2014 meta-analysis comparing robotic to laparoscopic adrenalectomy confirmed that the transperitoneal approach is the most widely implemented method with both techniques (72.5 % of robotic adrenalectomies, 75.5 % of laparoscopic adrenalectomies, $p=0.27$). Conversion rates, OR time and incidence of post-operative complications did not differ statistically for the two techniques. However, laparoscopically treated patients did experience heavier intraoperative bleeding and required longer hospitalization than patients who underwent robotic adrenalectomy [24].

APPLICATIONS OF IMAGING IN ADRENAL SURGERY

Differential diagnosis between benign and malignant lesions is accomplished with the contribution of Radiology. With the progress of technology, current imaging equipment can offer highly detailed anatomical information and clues about a lesion's physiological behaviour. All of the above assist the Surgeon in implementing the most appropriate procedure for the patient.

1. Adrenal Cortical Adenoma

Adrenal cortical adenoma is usually a benign mass and in most cases nonfunctional. If the lesion is active it produces symptoms related to hypersecretion of cortisol or aldosterone, while its potential malignancy is increased with size ($>3\text{cm}$). Sex-hormone secreting tumors have commonly malignant behavior.

They produce androgens, estrogens or both. For androgen secreting tumors, high blood concentration of testosterone and DHEA-s levels combined with urine 17-ketosteroids forge the diagnosis. For estrogen secreting tumors, high blood concentration of estrogens and urine 17-ketosteroids serve the same cause.

Imaging is crucial in the evaluation of incidentalomas. It's also valuable to correlate current and previous imaging, as malignant lesions tend to change over time, unlike non-malignant ones. Adrenal lesions can be divided to typical and atypical according to their appearance. [25]

Typical adenomas: small: $< 3\text{ cm}$, homogeneous and with low density.

Atypical adenomas:

$> 3\text{ cm}$, may present: hemorrhage, calcification, necrosis, absence of adipose tissue

$> 4\text{ cm}$: 70% malignant (excluding adrenal myelolipomas which are easily recognized due to adipose tissue presence, and pheochromocytomas which are usually recognized with biochemical markers.

$> 6\text{ cm}$: 85% malignant potency [25]

Radiographic Approach

Computed Tomography (CT): Adrenal masses are usually first identified by CT scan. Most of adrenal adenomas (about 70%) contain significant intracellular fat and therefore CT presents with high sensitivity and specificity in their identification. Calculating the mean Hounsfield units (HU) of an adrenal lesion first at non-enhancing CT (between -10 Hounsfield units and 10 HU) and early and delayed enhanced CT using the region of interest. A washout rate, usually of 15-min-delayed CT, is most useful in the diagnosis of adrenal adenomas. CT is the most reliable test to differentiate between benign and malignant adrenal lesions. However, the diagnosis of lipid-poor adenomas is quite harder [26].

Figure 1. Right adrenal mass. Thin-section non-enhanced CT image, attenuation levels are at 15 HU, because of abundant intracytoplasmatic lipid in the cortex.

Figure 2. Right adrenal mass. Thin-section enhanced CT image. During the arterial phase of enhancement, density measurements reach 122 HU, dropping to 72 HU during the portal phase of enhancement.

Magnetic Resonance Imaging (MRI): MRI is mainly utilized when CT results are inconclusive. Chemical shift imaging demonstrates a high diagnostic reliability, as it is highly sensitive to little amounts of intracellular fat and therefore a signal intensity drop can be measured in the majority of adenomas. The adenoma can also be compared in and out of phase, using other adjacent tissues as reference (apart from the liver). Restricted diffusion is usually detected in malignant lesions [27] (Figures 3, 4).

Figure 3. Adrenal adenoma. A coronal T1-weighted out-of-phase MR image shows relative signal loss within the lesion, when compared with the signal loss of the spleen and paraspinal muscle. The signal loss on opposed-phase images related to intracellular lipid is based on phase cancellation of fat and water protons within the same voxel.

Figure 4. Adrenal adenoma. An axial T1-weighted in-phase MR image shows a large homogeneous mass in the left adrenal gland (arrow) with signal intensity similar to that of the paraspinal muscle or spleen.

2. Adrenal Myelolipoma

Adrenal myelolipoma is a rare non-malignant, non-secreting tumor usually appearing in the 5th-6th decade of life. In the majority of cases it is unilateral and represents 3-5% of all primary adrenal tumors [28].

Radiographic Approach

Ultrasound: Adipose tissue distribution in the lesion, determines its sonographic image. Most commonly they are depicted as a heterogeneous mass of both hyper- and hypoechoic components. [28].

Computed Tomography (CT): Myelolipomas typically appear as relatively well-circumscribed adrenal masses. They contain fatty components, the amount of which may vary. In many cases, small punctate calcifications can be seen, as well as regions of higher attenuation (in cases of present hemorrhage - seen in larger lesions) [28-29].

Magnetic Resonance Imaging (MRI): T1: typically hyper-intense due to fat contents, T1 (FS): typically shows fat suppression, T1 + (Gd): shows striking enhancement, T2: intermediate to hyperintense (varies depending of hemorrhage products), in and out of phase: out of phase imaging may demonstrate signal loss in mixed components masses [28], [30].

3. Adrenal Cortical Carcinoma

Adrenal cortical adenoma is a very rare but aggressive tumor (incidents 1-2 cases per million). Clinical manifestations are present in around 50-60% of all cases and are attributed most commonly to cortisol excess (Cushing syndrome). Fewer cases are presented with symptoms of hyper secretion of the remaining cortical hormones (aldosterone, sex hormones). Usually at the time of the diagnosis local spread or distant metastasis are already present [31-32].

Radiographic Approach

Focal extensions can occur into the renal vein, as wells as in the IVC and liver [31-32].

Ultrasound: A well-defined adrenal mass is usually observed, with small lesions being homogeneous and larger ones rather heterogeneous, because of necrosis or hemorrhage [31-32].

Computed Tomography (CT): Adrenal carcinomas are usually large masses (> 6 cm), variably enhanced in CT, because of their irregular shape and central hemorrhagic and necrotic areas. Smaller carcinomas look much similar to adenomas [31-32].

Magnetic Resonance Imaging (MRI): It is usually used to determine the presence of metastases where CT may be inconclusive. The administration of gadolinium reveals the heterogeneity of the mass due to the presence of hemorrhagic components [31-32].

Angiography: Selective arteriography can distinguish renal from adrenal tumors by identifying the source of the primary vascular supply, when the organ of origin cannot be identified [31-32].

4. Pheochromocytoma

Pheochromocytoma is a neuroendocrine tumor of the adrenal medulla. Pathological origin can be traced to adrenal chromaffin cells which are derived from the neural crest. During embryological development, these cells migrate to the adrenal medulla (80-90%) and the rest can be found in the ganglia of the Autonomous Nervous System (ANS). [33] Usually pheos follow the ‘rule of 10’’: 10% bilateral, 10% malignant, 10% are found in children 10% familial (associated with either MENII , Von Hippel-Lindau disease, Neurofibromatosis 1, familial types of pheochromocytomas), 10 % located in the ANS ganglia (paragangliomas), 10% are not associated with hypertension [33].

Cardinal clinical manifestations are headaches and blood pressure disorders: 1) typically paroxysmal type, 2) constant severe hypertension is more common in malignant pheos, 3) even hypotension can occur in tumor necrosis when large quantities of epinephrine are released in the circulation leading to massive vasodilation by β - receptor activation. Other clinical symptoms include tachycardia, palpitations, anxiety, dyspnea, diaphoresis, vomiting, weight loss and hyperglycemia [33].

Diagnostics tests include 24 hour urine collection and measurement of metanephrine-VMA-catecholamine levels [33].

Radiographic Approach

Adrenal tumors are usually larger than 3cm (~5 cm) and therefore easy to identify. However, small extra-adrenal tumors are quite challenging to find. Malignancy can be evaluated from the image only when local tissue invasion or metastases are present [34-35] (Figure 5).

Ultrasound: The appearance is variable (solid/cystic/mixed) [34-35].

Figure 5. Pheochromocytoma. Surgical specimen.

Computed Tomography (CT): CT is highly sensitive and therefore the first imaging modality to be used. Pheochromocytomas are usually large and heterogeneous, with necrotic areas, cystic modifications and maybe calcifications. Rich enhancement is typically noted [34-35].

Magnetic Resonance Imaging (MRI): MRI demonstrates the highest sensitivity in identifying pheochromocytomas and most valuable in cases of extra-adrenal localization of tumors. T1 signal will be more heterogeneous in necrotic or hemorrhagic areas with the rest of the adrenal being slightly hypo-intense. T1 C+ (Gd): persistent heterogeneous enhancement. T2 markedly hyper-intense: light bulb sign and areas of necrosis / haemorrhage / calcification would change the signal [34-35].

Nuclear medicine: Pheochromocytomas, even extra-adrenal ones, can be imaged using various agents. The specificity of this method is not very high though and its spatial resolution is limited [34].

Octreotide (somatostatin) scans: Somatostatin receptors are expressed in over 70% of pheochromocytomas. These method lacks specificity though as the same receptors can also be found in kidneys, areas of inflammation and other glands, making interpretation quite difficult. Imaging is executed 4 hours after intravenous infusion [34].

Positron Emission Tomography (PET): PET scan is considered to be highly sensitive [36].

5. Neuroblastoma

Neuroblastoma is the 4th most common malignancy in childhood. [6] Most children are diagnosed under the age of five. It's a malignancy that arises from nerves of the sympathetic system. [6]

They can be located anywhere along that path. Around 30% of these tumors are located in the adrenal glands. (Figures 6, 7) Other sites may include i) paraspinal ganglia, ii) thoracic cavity and pelvic cavity. [6] Symptoms and signs are usually restricted to a palpable abdominal mass which is only rarely accompanied with pain. [6] Less commonly, neuroblastomas are accompanied by: opsoclonus, Hutchinson syndrome due to bone metastases, Pepper syndrome which is in fact hepatomegaly due to extensive liver metastases, blueberry muffin syndrome presenting with multiple cutaneous lesions. [37-38] Diagnostic results include in 90% of cases elevated VMA, HVA in 24 hour urine collection sample [38].

Figure 6. Ganglioneuroma. Surgical specimen.

Figure 7. Ganglioneuroma. Surgical specimen (dissected).

Radiographic Approach

Ultrasound: Neuroblastoma is depicted as a heterogeneous mass with internal vascularity, necrotic areas and calcification. [37-38]

Nuclear medicine: Agents used for diagnosis and staging:

- pentetreotide labeled to Indium-In111 (somatostatin analog) – nonspecific
- MIBG (metaiodobenzylguanidine labeled to Iodine-123) – screening for metastatic recurrence.
- Tc-99m MDP-mostly used in evaluating metastases [37-38].

Figure 8. Ganglioneuroma. A coronal T1-weighted out-of-phase MR image shows no signal loss within the lesion, presence of intracellular lipid.

Figure 9. Ganglioneuroma. Axial T1weighted image heterogeneously intermediate, distinguished mild capsule.

Figure 10. Ganglioneuroma. Axial T1 C+ (Gd) weighted image with heterogenous enhancement.

Computed Tomography (CT): A heterogeneous mass with calcifications is usually noticed. The tumor displaces, compresses or invades adjacent structures depending on its malignant potential [37-38].

Magnetic Resonance Imaging (MRI): MRI assesses CNS involvement, as well as determines the organ of origin. T1: heterogeneous and iso- to hypo- intense. T1+ (Gd): variable and heterogeneous enhancement. T2 heterogeneous and hyper-intense with cystic/necrotic areas of notably high intensity [37-38] (Figure 8, 9, 10).

6. Adrenal Metastases

Most common primary tumors which produce adrenal metastases are: lung cancer, colorectal cancer, breast cancer, pancreatic cancer and others like renal cell carcinoma, hepatocellular carcinoma, and malignant melanoma [39].

Radiographic Approach

Computed Tomography (CT): Metastases have variable appearance in a CT scan. The enhancement washout percentage is usually <50% and is similar to that of lipid-poor adrenal adenomas in cases of renal cell or hepatocellular carcinoma. [32], [39] *Magnetic Resonance Imaging (MRI)*: Signal characteristics may vary; the most common ones include: T1: usually have a low signal intensity. T1 C+ (Gad): a progressive enhancement after administration of contrast material. T2: usually have a high signal intensity [32], [39].

7. Other Rare Adrenal Lesions

Ganglioneuromas

These constitute benign tumors of the Sympathetic Nervous System (SNS). They are extremely rare and usually asymptomatic. Majority of cases are diagnosed incidentally [37].

Radiographic Approach

Computed Tomography (CT): Findings are compatible with well circumscribed, solid, encapsulated masses. Lesions tend to be iso- to hypo-attenuating compared to muscle signals. May demonstrate calcifications (~ 20%) [37].

Magnetic Resonance Imaging (MRI): T1 - tends to have homogeneously low or intermediate signal. T2 - tends to have heterogeneously intermediate or high signal. T1 C+ (Gd) - variable ranging from none to heterogeneous enhancement. ADC - ADC values tend to be higher to that of a neuroblastoma [37].

Adrenal Cysts and Pseudocysts

Adrenal cysts constitute rare (incidence of 0.06% to 0.18% in autopsy studies), benign, and usually nonfunctional lesions. They tend to be large at presentation (> 6 cm), and at times hard to distinguish from renal upper-pole cysts. They are often the outcome of prior adrenal trauma or hemorrhage. Adrenal pseudocysts do not contain an epithelial wall but rather a fibrous sheath. They compromise about 40% of adrenal cysts and more likely than simple cysts to be asymptomatic [26-28].

Radiographic Approach

Symptoms may develop if the lesion is very large or in the event of hemorrhage, infection, or rupture. Simple endothelial-lined cysts are more often well-defined cysts with thin or imperceptible walls that show fluid density on CT and are homogeneously hypointense on T1weighted images and hyperintense on T2-weighted images. No enhancement occurs after the administration of intravenous (IV) contrast. Pseudocysts may have a more heterogeneous appearance because of the presence of blood products, septations, and

calcifications. On MRI, blood products present variable T1- and T2-weighted signal intensities, depending on the stage of degeneration. Calcifications are better appreciated on CT images [26-28].

Hemangiomas

Hemangiomas are benign lesions. Theoretically they can develop at any age in both sexes, but they do are more common in 40-70 year old female patients. As a rule these remain asymptomatic until and if they grow large.

Severe spontaneous bleeding is not a common phenomenon. Hemangiomas are predominantly solid tumors with cystic central areas and calcifications. Peripheral enhancement is noted after intravenous contrast administration [40].

CONCLUSION

In contemporary medicine, no one can function as a sole unit. Physicians need to cooperate, with each one offering their expertise for the benefit of the patient. In this spirit of holistic approach to healing, the surgeon acts a leading player of a team, which includes anaesthesiologists, internists, pathologists, surgical nurses and of course radiologists. It is with sophisticated imaging equipment and experienced diagnosticians that Surgeons acquire decisive information which help them understand the unique anatomical and physiological background of the patient's disease. Indeed, operating on adrenal lesions without detailed radiologic examinations could be catastrophic for a patient especially in cases of pheochromocytomas or malignancies. Indisputably, adrenal cysts and myelolipomas have characteristic imaging findings which lead to a safe diagnosis. Often, the specific diagnosis of adrenal adenoma can also be made based on CT attenuation measurements, CT washout criteria, or signal loss on opposed-phase MR imaging.

However, it is imperative to avoid blind adherence to imaging studies as they do have sensitivity and specificity limitations. Surgeons should embrace this endogenous flaw and invest in their training. In order to be considered an endocrine surgeon one is obliged to master at least open and laparoscopic techniques, whilst maintaining a high-volume patient load per year. Taking everything into account, the quality of care offered to patients with adrenal disease will boost exponentially with the combination of in-depth surgical training and sincere cooperation with other medical specialties.

CONFLICT OF INTEREST

The authors report no conflict of interest. Obtained funding: Not applicable.

ABSTRACT

The increasing complexity of hepatobiliary diseases, benign or malignant, that a surgeon is called to treat, has led to a deeper understanding of the importance of a multidisciplinary approach. Imaging, with its various modalities, plays a central role in the diagnosis and management of hepatobiliary malignancies. An integral part of this remains the communication between the surgeon and the radiologist regarding the exact findings, as well as the different types of management, ranging from surgery to interventional radiology. The goal remains to find the best treatment for the patient. This chapter will present the existing preferences regarding the diagnosis and management of one of the main primary hepatobiliary malignancies, which is hepatocellular carcinoma (HCC). Additionally, we will examine certain special cases (such as the imaging of the early lesion or standardization of imaging reporting), as well as report on the possibilities offered by newer imaging developments. Finally, we will also address the identification and management of a focal hepatic lesion. Overall, the goal is for this chapter to be part of the interplay and the dialogue between the surgeon and the radiologist, in terms of information that needs to be communicated and the best way to do that.

THE ROLE OF IMAGING IN THE MANAGEMENT OF HEPATOCELLULAR CARCINOMA (HCC)

Introduction

Hepatocellular carcinoma (HCC) continues to increase in incidence, becoming the fifth most common cancer worldwide and responsible for slightly less than 10% of all cancers [1]. The major risk factor for HCC remains cirrhosis, irrespective of its etiology.

Specifically, a variety of causes, such as alcoholic liver disease, viral hepatitis, cholestatic liver diseases, autoimmune and metabolic disorders and the nonalcoholic steatohepatitis, all represent chronic liver insults, which in due time will change the liver architecture and physiology and lead to cirrhosis, if left untreated. Once cirrhosis occurs, irrespective of the causative factor, it is a risk factor for HCC. This process of carcinogenesis in the liver is a progressive one, and as such there would be great value in being able to recognize it at an early stage, something which is made harder by the presence of the cirrhotic nodules.

Additionally, these patients now have to face the dual threat of a hepatic malignancy, with the background of a declining liver function. The importance of HCC worldwide and the need for early diagnosis and successful treatment, have placed a heavy burden on the different imaging modalities. The role of hepatobiliary imaging is critical in the management of HCC, as it can make the difference when deciding whether a hepatic resection or an orthotopic liver transplantation (OLT) will be needed for treatment.

An example of the importance of accurate radiological diagnosis for HCC, is its role in deciding the need and the urgency for OLT for a patient. Specifically, currently in the United States and in many other countries, the place in the waiting list for a liver transplant is determined by the Model for End-Stage Liver Disease (MELD) score, which is basically an approximation of the patient's hepatic synthetic function by including the INR, serum bilirubin and serum creatinine into an equation. This will lead to a score of 6-40, with 6 representing normal liver function and anything over 30 representing an over 90% possibility of mortality in the next 3 months. Although this type of calculation is a relatively objective one, it does represent a problem for patients with cirrhosis and HCC. The reason is that in these patients, their hepatic function is usually well-preserved (and thus their MELD score is relatively low), whereas the more imminent danger for them is the HCC. If the disease progresses beyond certain criteria (usually the Milan criteria are the ones quoted most frequently with one lesion 5cm or less or 3 lesions none bigger than 3cm and no metastatic disease), then the patient cannot be transplanted and expect good results.

Based on this, the decision has been made in many countries using the MELD system to give extra points to patients with cirrhosis and HCC (if it is within criteria), in order to get them to an OLT sooner rather than later. However, in order to do that it is important to accurately diagnose the presence of HCC and liver biopsy is not an easy task for a small lesion in a cirrhotic patient. As a result, in over 95% of patients receiving these HCC exception points, the diagnosis of HCC was made using a good quality MDCT or MRI, thus underscoring the importance of radiological imaging for these patients. Additionally, advances in interventional radiology have added significant weapons (such as percutaneous radiofrequency or microwave ablation or chemoembolization) to the armamentarium of the hepatobiliary multidisciplinary management team.

As part of the overall progress, there are currently international guidelines, whereby dynamic cross-sectional hepatic imaging is considered diagnostic to the extent that a liver biopsy may not be needed [2]. Having said all that, we should stress that more questions have arisen, with the critical one being, what is the role of all this different radiologic modalities within the spectrum of therapeutic modalities for HCC. However, before answering this question, we need to review the existing radiological modalities, including their advantages and disadvantages and the future prospects.

THE ROLE OF DIFFERENT IMAGING MODALITIES IN THE DIAGNOSIS AND MANAGEMENT OF HCC

Ultrasound

The key to achieving long-term success in the management of HCC is early diagnosis. The majority of international societies have agreed that a major step towards this goal is the development of ultrasound surveillance programs, especially in patients who are at higher risk, such as cirrhotics [3, 4]. The major challenge is identifying a dysplastic lesion in the background of a cirrhotic liver, and then following it closely with serial exams, as approximately a third of them will develop into a malignancy [5]. Ultrasound offers the advantage of a practical, easily repeatable, cost-conscious method of being able to follow these patients, without the complications that can (rarely) arise in the other more complex methods. The disadvantage is the subjective nature of ultrasound, as it is very much dependent on the experience of the person performing it. One of the improvements has been the use of contrast-enhanced ultrasound, which used a variety of microbubble-based contrast agents to correctly diagnose HCC. These agents offer the advantage of being able to visualize and evaluate tumor hemodynamics, including the hypervascularity which is frequently associated with HCC in the arterial phase [6]. The increasing experience and aptitude with contrast-enhanced ultrasound may very soon challenge the primacy of dynamic CT for the diagnosis of HCC.

Multidetector Computed Tomography (MDCT)

One of the most frequent challenges in making the diagnosis of a liver lesion, is deciding between a primary HCC or a metastatic lesion. The way to make this differentiation is through the use of a triple-contrast CT, with an arterial, a portal venous and an equilibrium phase. The rationale is that HCC is characterized by hypervascularity during the arterial phase and contrast washout during the portal venous and equilibrium phases. On the other hand, hepatic metastatic disease will be more prominent during the portal venous phase, thus allowing the differentiation between HCC and liver metastatic disease. The significance of the hypervascularity of HCC is that for the majority of associations, such as the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL), this pattern of contrast uptake (the arterial phase “wash in” and the portal venous phase “wash out”) is considered diagnostic for HCC, when the lesions are

2cm in diameter or bigger. The problem and the debate is for smaller lesions. Specifically, whereas for the AASLD the MDCT is sufficient for all lesions > 1cm, the EASL guidelines and for lesions 1-2cm require a second study for the confirmation, based on data from prospective studies [3, 4]. This is where Magnetic resonance imaging (MRI) comes into play, as it can offer a slightly improved accuracy or at least confirmation for lesions < 2cm. Adding to this problem is the fact that smaller lesions, such as early HCC or borderline ones, may not exhibit the typical HCC contrast uptake pattern and show isoattenuation or even low attenuation to the liver parenchyma in the arterial phase, thus making the MDCT less helpful.

Magnetic Resonance Imaging

Although there is a “typical” pattern for HCC in MRI, with lesions being hypointense on T1-weighted and hyperintense on T2-weighted images, this also depends on the degree of lesion differentiation, as early HCC may often exhibit hyperintensity on T-1 weighted images and iso- to hypointensity on T2-weighted images. Although it may seem counterintuitive, international guidelines do not support MRI over MDCT, as in most studies the diagnostic accuracy of both is similar [7]. The one area where there may be an advantage for the use of MRI, is for the smaller nodules (< 2cm) as it was mentioned before, as well as the fact that there are newer MRI techniques, such as the diffusion-weighted imaging (DWI) and newer hepatobiliary (HB) contrast agents, such as gadopentetate dimeglumine (Gd-EOB-DTPA), which allow for greater diagnostic capability [8-10].

These hepatobiliary agents use a delayed hepatobiliary phase, as they are transported into the hepatocytes. The use of Gd-EOB-DTPA, which is a T1-shortening, extracellular and hepatocyte contrast agent, with its increased accuracy have made it extremely useful in the case of lesions smaller than 2cm and for borderline lesions, such as those represented by hypovascular HCC [11, 12]. This increased sensitivity using the hepatobiliary contrast agents (such as Gd-EOB-DTPA) can be critical in patients with early HCC, as it was shown in a recent paper where treatment was modified in up to 12% of the included patients, based on information obtained by HB-enhanced MRI [13]. The value of MRI increases even more if we consider DWI MR sequences, which evaluate the random motion of water in biological tissues. This way, and because of the restriction of water molecules in the tumor, those areas appear brighter, and have made DWI a valuable resource for borderline and hypovascular lesions [14, 15]. Overall, the MRI is an excellent and safe study for HCC, and liver lesions in general. However, it remains an expensive imaging modality, and as such it is important to ensure that it is used wisely and that both the referring physician and the radiologist know what to ask for and what to look for, respectively.

Positron Emission Tomography

Positron Emission Tomography (PET) differs from CT and MRI, in the sense that it is more dependent on the molecular changes that occur in the tumor and normal tissue cells, versus anatomical changes.

The basis for the emphasis on these molecular changes has to do with the fact that tumors are metabolically different from normal tissue and, as such, the uptake and metabolism of certain molecules (glucose for example) can be used to identify cancerous changes.

Although PET is not an anatomic study, it is used in combination with CT (PET-CT), in order to locate “geographically” in the liver the area with the higher uptake. Despite its many promises, a recent review study of available literature, has shown that PET may not be ideal for identifying primary hepatic malignancies [16].

CHALLENGES IN THE ROLE OF IMAGING FOR HCC

The different imaging techniques that were described above represent the main ones involved in the diagnosis, staging and treatment of HCC. However, the deeper we delve into the variety of these imaging techniques, it becomes obvious that the more questions arise, which essentially point out the finer nuisances of these techniques, as well as the opportunities that they may offer. Next, we will discuss some of these challenges and opportunities that are presented by these current imaging methods.

Hepatocarcinogenesis

The presentation of a HCC is the result of the progression from a dysplastic nodule in a cirrhotic liver, to one with overt malignancy. This evolution is characterized by the development of new arteries, which are not accompanied by bile ducts, which allows the differentiation between a regenerative and a dysplastic nodule [17, 18]. It is interesting that there appears to be a correlation between the number of new arteries and the degree of HCC differentiation, especially in the case of smaller lesions. This, combined with the decrease in the number of Kupffer cells, has enabled current imaging techniques to observe and define the different phases and steps of hepatocarcinogenesis, thus playing a critical role in earlier detection [2].

Limitations of the Different Management Systems and the Need for Standardization

There are approximately a total of 19 diagnostic systems and guidelines published or presented between 2001 and 2013 for the diagnosis and management of HCC [19, 20]. The majority of these guidelines contain imaging-based diagnostic systems, which have become increasingly more detailed and sophisticated, given the corresponding progress and accuracy in imaging technology. In the earlier systems the hypervascular appearance of a lesion was sufficient, whereas in the more recent ones issues such as capsule appearance or contrast washout appearance play a more important role.

Some of the issues between the different systems have to do with terminology, whereas others have to do with more basic disagreements regarding the importance of different factors in the diagnosis and management.

These systems may reflect differences in clinical practice, contrast agents used, tumor biology, cultural preferences and geographical patterns. Additionally, these systems may not be detailed enough to help radiologists make the proper diagnosis, as they may place more emphasis on the classical appearance of HCC and not include the various subtypes, whose appearance may be more perplexing. Also, the European and the US systems, ask for a biopsy in cases of hypo- or iso-enhancing arterial phase lesions, given the fact that a 100% positive predictive value for these features does not exist. On the other hand, in 2008 the American College of Radiology came up with the Liver Imaging Reporting and Data System (LI-RADS), which would classify such lesions (hypo- or iso-enhancing) as LR 4, which is possible HCC [21]. Finally, most systems, with the exception of the Japan Society of Hepatology, do not include hepatobiliary phase MRI, thus making it harder, possibly, to diagnose smaller lesions. The reason is that HB phase MRI provides functional data on a lesion, such as water molecule motion and hepatobiliary cellular function, thus making the identification of hypovascular lesions possible.

No matter what these differences, the fact remains that we are lacking a common language to discuss the diagnosis, staging and management of HCC. This problem becomes an even bigger challenge, if we consider the continuous evolution of imaging techniques and the need to find the proper place for the newer methods by recognizing their advantages, as well as their limitations.

Assessing Response to Locoregional and Systemic Therapy for HCC

Locoregional treatments for HCC represent an important part of the armamentarium of the multidisciplinary team of physicians caring for the patient. The two main locoregional treatments include transarterial chemoembolization (TACE) and ablation methods, which include radiofrequency ablation or microwave ablation among others. TACE can be used in patients with hepatocellular carcinoma at various stages of the disease. Specifically, it can be used as first line treatment for unresectable intermediate stage HCC, or as a bridge to liver transplantation (avoid an increase in the tumor, while the patient is on the waiting list), or as a downstaging method. In the case of the latter, the goal is to reduce the tumor burden through the use of TACE, thus making the patient eligible for resection of liver transplantation [22-24]. Additionally, in patients with advanced disease, TACE can be used as a temporizing measure, in the sense that it can control the growth of the tumor or the symptoms caused by it and do that in a manner that does not affect hepatic function significantly (and thus quality of life for the patient) and can be repeated.

Radiofrequency ablation (RFA) is one of the main tumor ablation methods and can be done either percutaneously or surgically (open or laparoscopic surgery), depending on the size and location of the lesion. It is usually performed on patients with small HCCs, stage A1 to A3 by Barcelona Clinic Liver Cancer (BCLC), in order to avoid surgical resection [25]. It can also be used for resection of lesions, as well as in combination with other invasive techniques such as microwave ablation [26]. According to the American Association for the Study of Liver Diseases (AASLD) guidelines, RFA is a safe and effective method to treat patients with advanced liver tumors. For up to 4-5 hepatic lesions, less than 3cm in diameter, initial complete response rates of more than 90% and local tumor progression rates between 10-20% have been reported [27, 28].

Both of these types of locoregional treatment have proven to be a valuable tool for the management of patients at different stages of HCC and for different purposes. One of their most critical advantages, is the fact that they can be repeated with acceptable safety margins.

However, in order for this to be meaningful, it is essential to be able to evaluate the result of these treatments radiologically. The methods used most frequently are cross-sectional imaging with MRI and CT. The information needed in order to accurately assess the response to the therapy includes evaluation of the tumor size (including the margins involved and the areas of necrosis), the presence of any embolization agents used or not, and the detection either of remaining tumor (with the challenge being to identify whether it is active or not) or of tumor recurrence [29].

Portal Vein Embolization

Portal vein embolization (PVE) represents an extension of the role of embolization in the management of HCC. Specifically, there are patients where a hepatectomy to remove the HCC, may leave behind a liver remnant that is less than 40% (in a healthy liver) or 20-25% (in a cirrhotic liver), thus placing the patient's survival in jeopardy, as there is a significant risk of hepatic decompensation.

In order to improve on this predicament, one option is PVE, whereby interventional radiologists embolize the portal vein branch on the side of the tumor. In approximately 4-6 weeks, this leads to a hypertrophy of the healthy liver lobe, which will become the liver remnant after the resection, of about 10-30%, thus potentially allowing the liver resection to proceed [30]. Obviously, the overall process is significantly more complicated as it has to be performed with accuracy and there are several factors that play a role including the experience of the radiologist performing it, the type of embolization agent used, managing the complications that can occur and identifying the optimal timing to proceed with the resection.

Image-Guided Surgery

One of the challenges, which is more evident with the use of neoadjuvant treatment for hepatic metastatic disease, is the fact that although the lesions may disappear on the CT, cancer cells may still be present in approximately one third of the patients [31]. These patients may end up with recurrent disease, and as a result many favor a liver resection for the potentially involved segment. Another situation which may require delicate maneuvers, is that of a non-anatomic hepatectomy, where the involved part of the liver is resected, but not along the division of Quinaud, and essentially leaving behind as much parenchyma as possible. To be able to do this successfully, it is important to have accurate imaging of the liver "topography," which is not very easy with the routine cross-sectional methods, such as CT and MRI, given the complex 3-D anatomy of the liver with all its variations.

The answer to these problems could be the use of image-guided surgery, whereby preoperative medical images are registered with intraoperative landmarks, in order to provide a 3-D image of the liver that will allow the surgeon to proceed with the resection in an interactive manner, that is be aware at every point of the resection of the relation to the vascular and biliary structures that may be encountered [32].

The steps required include the preoperative processing of the CT or MRI images, obtaining information on the specific liver anatomy and matching the pre- and intra-operative data [33]. This last part, the matching or registration process, which essentially involves the linking of the preoperative imaging information with the real-time location of the resection plane during the surgery, is the hardest one to accomplish. There is significant interest in this endeavor, including several commercial programs, and so the hope is that there will continue to be improvements of the system. It is important to point out that the majority of the planning regarding the resection plane and strategy is done preoperatively using the 3-D imaging.

CONCLUSION

We have examined in this chapter the current techniques used for imaging of the liver, with special emphasis on the diagnosis, staging and treatment of hepatocellular carcinoma. Additionally, we have examined some of the developments in this field that represent significant achievements, as well as future challenges.

Obviously, the role of imaging techniques in hepatic surgery is critical and it continues to evolve as technology progresses. However, it is essential to identify for all the new techniques their proper place in the armamentarium of the multidisciplinary team dealing with this complex disease. The reason is that by knowing their advantages, as well as their limitations, only then can we offer our patients the best, all-around care and do that in a sensible manner.

ABSTRACT

The pancreas is an organ that has presented surgeons with significant challenges as both benign and malignant lesions, given the location and physiology of the organ, require significant expertise for both diagnosis and treatment. This chapter will present the most current imaging technology available for pancreatic disease and provide examples of how the surgeon and the medical team can choose the best one for each possible situation.

INTRODUCTION

The pancreas is a retroperitoneal organ that lies in an oblique position, sloping upward from the C-loop of the duodenum to the splenic hilum. In an adult, the pancreas weighs 75 to 100 g and is about 15 to 20cm long. The fact that the pancreas is situated so deeply in the abdomen and is sealed in the retroperitoneum explains the poorly localized and sometimes ill-defined nature with which pancreatic pathology presents.

In this chapter, we start with a brief overview of basic pancreatic anatomy and then we present thirteen common pancreatic conditions that may require surgical intervention and

* Corresponding Author's Email: narkado@ hotmail.com.

analyze the role of the various imaging modalities in the diagnosis and planning for surgery. All images used in this chapter originate from the authors' personal archives.

Pancreatic Anatomy

An understanding of embryology is required to appreciate the common variations in pancreatic duct anatomy. The pancreas is formed by the fusion of a ventral and dorsal bud. The duct from the smaller ventral bud connects directly to the common bile duct (CBD) while the duct from the larger dorsal bud drains directly into the duodenum. The duct of the ventral anlage becomes the duct of Wirsung, and the duct from the dorsal anlage becomes the duct of Santorini. With gut rotation, the ventral anlage rotates to the right and around the posterior side of the duodenum to fuse with the dorsal bud. The ventral anlage becomes the inferior portion of the pancreatic head and the uncinate process, while the dorsal anlage becomes the body and tail of the pancreas. The ducts from each anlage usually fuse together in the pancreatic head such that most of the pancreas drains through the duct of Wirsung, or main pancreatic duct (MPD), into the common channel formed from the bile duct and pancreatic duct. In 10% of patients, the ducts of Wirsung and Santorini fail to fuse. This results in the majority of the pancreas draining through the duct of Santorini and the lesser papilla, while the inferior portion of the pancreatic head and uncinate process drains through the duct of Wirsung and major papilla. This normal anatomic variant, which occurs in one out of 10 patients, is referred to as pancreas divisum. The MPD is usually only 2-3mm in diameter and runs midway between the superior and inferior borders of the pancreas. The MPD joins with the CBD and empties at the ampulla of Vater or major papilla, which is located on the medial aspect of the second portion of the duodenum. When the accessory pancreatic duct or lesser duct drains into the duodenum, a lesser papilla can be identified approximately 2cm proximal to the ampulla of Vater.

The blood supply to the pancreas comes from multiple branches from the celiac and superior mesenteric arteries (SMA). The common hepatic artery (CHA) gives rise to the gastroduodenal artery (GDA) before continuing toward the porta hepatis as the proper hepatic artery. The GDA becomes the superior pancreaticoduodenal artery as it passes behind the first portion of the duodenum and branches into the anterior and posterior superior pancreaticoduodenal arteries. As the SMA passes behind the neck of the pancreas, it gives off the inferior pancreaticoduodenal artery at the inferior margin of the neck of the pancreas. This vessel quickly divides into the anterior and posterior inferior pancreaticoduodenal arteries. The superior and inferior pancreaticoduodenal arteries join together within the parenchyma of the anterior and posterior sides of the head of the pancreas along the medial aspect of the C-loop of the duodenum to form arcades that give off numerous branches to the duodenum and head of the pancreas. Therefore, it is impossible to resect the head of the pancreas without devascularizing the duodenum, unless a rim of pancreas containing the pancreaticoduodenal arcade is preserved. Variations in the arterial anatomy occur in one out of five patients. The right hepatic artery, CHA, or gastroduodenal arteries can arise from the SMA. In 15 to 20% of patients, the right hepatic artery will arise from the SMA and travel upwards toward the liver along the posterior aspect of the head of the pancreas.

It is important to look for this variation on preoperative computed tomographic (CT) scans and in the operating room so the replaced hepatic artery is recognized and injury is

avoided. The body and tail of the pancreas are supplied by multiple branches of the splenic artery. The splenic artery arises from the celiac trunk and travels along the posterior-superior border of the body and tail of the pancreas toward the spleen. The inferior pancreatic artery usually arises from the SMA and runs to the left along the inferior border of the body and tail of the pancreas, parallel to the splenic artery.

Three vessels run perpendicular to the long axis of the pancreatic body and tail and connect the splenic artery and inferior pancreatic artery. They are, from medial to lateral, the dorsal, great, and caudal pancreatic arteries. These arteries form arcades within the body and tail of the pancreas, and account for the rich blood supply of the organ.

The venous drainage of the pancreas follows a pattern similar to that of the arterial supply. The veins are usually superficial to the arteries within the parenchyma of the gland. There is an anterior and posterior venous arcade within the head of the pancreas.

The superior veins drain directly into the portal vein (PV) just above the neck of the pancreas. The posterior inferior arcade drains directly into the inferior mesenteric vein (IMV) at the inferior border of the neck of the pancreas. The anterior inferior pancreaticoduodenal vein joins the right gastroepiploic vein and the middle colic vein to form a common venous trunk, which enters into the superior mesenteric vein (SMV).

1. ANNULAR PANCREAS

Definition

Annular pancreas refers to a ring of pancreatic tissue that encircles mainly the second part of the duodenum. This congenital anomaly of the pancreas usually manifests in neonates or remains asymptomatic until adulthood [1].

Associated congenital abnormalities consist of intestinal malrotation, imperforate anus, esophageal atresia, duodenal stenosis, Down syndrome and cardiovascular disorders.

Surgical Interventions

- ✓ Retrocolic duodenojejunostomy/gastrojejunostomy in pediatric population
- ✓ Surgical and interventional endoscopic procedures in adult population

Imaging Modalities

The role of imaging modalities in case of annular pancreas is to establish the diagnosis and differentiate other causes which can produce "narrow duodenal lumen."

Radiographic Findings

Plain x-ray of the abdomen reveals narrowing of descending duodenum. The classic "double-bubble" sign refers to a large proximal bubble describing the dilated stomach and a small distal one indicative of concomitant dilation of the duodenal bulb.

Fluoroscopic guided Barium Study depicts an extrinsic, eccentric defect on medial margin of the second part of the duodenum with concentric narrowing and dilation of the proximal duodenum [2]. Periapillary duodenal ulcer due to reverse peristalsis may be encountered in adults implying the presence of Zollinger-Ellison syndrome (ZES).

Ultrasonography

Real time U/S is only indicative of a nonspecific enlargement of pancreatic head.

Computed Tomography

CT findings are often non-specific suggesting pancreatic head enlargement along with central area of increased attenuation representing contrast within narrowed duodenal segments. Parallel gastric and duodenal dilatation with circumferential thickening of the wall as well as obstructing band of pancreatic tissue and dilated MPD, CBD and intrahepatic ductal system may be detected [3].

Magnetic Resonance Imaging

Fat-suppressed T1WI images describe normal pancreatic tissue encircling the duodenum. Subsequent MRCP depicts course and drainage pattern of pancreatic duct [4].

Angiography

Celiac angiography often reveals an anomalous branch from posterior pancreaticoduodenal artery that courses in a right and inferior direction supplying annular moiety.

Endoscopic Retrograde Cholangiopancreatography

ERCP describes a normal MPD in the body and tail of the pancreas communicating with small duct of pancreatic head encircling the duodenum.

On occasion, a small duct of the head originating on right anterior surface of duodenum, passing posteriorly around the organ and entering the MPD may be recognized.

Differential Diagnosis

- ✓ Duodenal carcinoma
- ✓ Postbulbar peptic ulcer
- ✓ Pancreatic carcinoma
- ✓ Duodenal hematoma

2. ACUTE PANCREATITIS

Definition

Acute pancreatitis is described as an acute inflammatory process of the pancreas with variable involvement of relevant regional tissues or remote organ systems. It can be initiated by several factors including biliary tract disease, alcohol, severe trauma, infectious disorders, ischemia, pancreatic duct obstruction and post-operative inflammation. Cases of hereditary pancreatitis have also been reported. Associated complications implicate fluid collection, extended edema, tissue destruction, fat necrosis and hemorrhage. Potential formation of pseudocyst, abscess or vascular pseudoaneurysm along with porto-splenic thrombosis or Disseminated Intravascular Coagulation (DIC) and sepsis has been suggested as major determinants of the outcome [5].

Surgical Interventions

- ✓ Drainage of infected pseudocyst
- ✓ Surgical debridement of infected necrosis

Imaging Modalities

The role of imaging modalities in case of acute pancreatitis is to establish the diagnosis and assess disease severity. Additional surgical intervention in case of necrotizing pancreatitis is also imaging dependent. If there is an indication of infection, then a CT- or US-guided fine-needle aspiration (FNA) should be performed for Gram's stain and culture of the fluid or tissue, and the indicated antibiotic therapy initiated.

Ultrasound

Abdominal U/S examination is the best imaging technique in confirming the presence of gallstones in suspected biliary pancreatitis. It may also determine extrapancreatic ductal dilations, pancreatic edema, swelling or fluid selection. Nevertheless, in the majority of affected patients U/S does not provide satisfactory results due to the presence of bowel gas which tends to obscure sonographic imaging of the pancreas.

Thus real time U/S could only reveal an enlarged hypoechoic gland or elucidate the formation of a pseudocyst or abscess. Therefore, additional CT is always implemented in order to distinguish milder categories of the disease from severe cases of necrotizing or infected pancreatitis and provide optimal care to the patient [6].

Computed Tomography

CT scanning with bolus intravenous contrast has become the gold standard for assessing the severity of acute pancreatitis. While clinically mild inflammation of the pancreas is correlated with interstitial edema with the microcirculation remaining intact and the gland presenting with uniform enhancement. In necrotizing pancreatitis, the microcirculation is disrupted. Therefore, the enhancement of the gland on contrast-enhanced CT (CECT) scan is considerably decreased (Figure 1). The presence of air bubbles is an indication of infected necrosis or abscess (Figure 2).

Figure 1. Abdominal CT in acute pancreatitis:-Pancreatic phase of enhancement: Decreased enhancement of the pancreas (less than 100HU) (green ROI).

Figure 2. Abdominal CT in acute pancreatitis - Pancreatic phase of enhancement: Air containing (arrow) peripancreatic fluid collection (asterisk) in a septic patient.

In conclusion, focal or diffuse enlargement of the pancreas along with heterogenous enhancement and infiltration of peripancreatic fat are major CT findings indicative of acute pancreatitis [7, 8]. The formation of pseudoaneurysm may also be apparent (Figure 3). Chest CT may reveal concomitant pleural effusions and basal atelectasis. Currently, intravenous, contrast-enhanced CT scanning is routinely performed on patients who are suspected of harboring severe pancreatitis, regardless of Ranson's criteria or APACHE scores. Imaging of acute pancreatitis necessitates not only an understanding of the disease subtypes and the myriad of associated complications but also familiarity with the appropriate radiologic nomenclature as defined by the Atlanta symposium and recently revised by the Acute Pancreatitis Classification Working Group. The use of standardized terminology will hopefully improve the communication between radiologists, gastroenterologists and surgeons to facilitate treatment schedule and lead to favorable outcomes for patients with acute pancreatitis as well as create uniformity for enrollment into research surveys [9, 10].

CT revised Atlanta classification: Five grades based on severity

- Grade A: Normal pancreas
- Grade B
 - Focal or diffuse enlargement of the gland
 - Contour irregularities and heterogeneous attenuation (Figure 4)
 - Absence of peripancreatic inflammation
- Grade C: Intrinsic pancreatic abnormalities and associated inflammatory changes in peripancreatic fat (Figure 5)
- Grade D
 - Small and usually single, ill-defined fluid collection
- Grade E
 - Two or more large fluid collections
 - Presence of gas in pancreas or retroperitoneum
 - Most important criterion: Presence and extent of necrotizing pancreatitis (non-enhancing parenchyma) (Figure 6)

Figure 3. Abdominal CT in acute pancreatitis: Pseudoaneurysm of the splenic artery (asterisk).

Figure 4. Abdominal CT in acute pancreatitis: Contour irregularity, heterogeneous attenuation of the pancreas.

Figure 5. Abdominal CT in acute pancreatitis: Intrinsic pancreatic abnormalities and associated inflammatory changes in peripancreatic fat (blue arrows). Cholelithiasis (thick white arrow).

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

MR findings refer to variable decreased signal intensity and gland enlargement on T1WI images. A heterogenous enhancement pattern along with the detection of a pancreatic pseudocyst contiguous with the MPD and potential vascular occlusion may be easily demonstrated. On fat suppressed T2WI images fluid collections as well as pseudocysts and necrotic areas are depicted hyperintense contrary to hypointense lesions including gallstones or intraductal calculi [11].

Furthermore, MRCP provides evidence of a dilated MPD or an associated pseudocyst. Finally, it is important to differentiate between an acute pseudocyst and walled-off pancreatic necrosis (WOPN) by accurate definition and characterization of the solid necrotic debris. Patients presenting with WOPN require more aggressive endoscopic intervention, in contrast to simple transmural drainage, which may prove adequate for therapeutic approach of pseudocysts [12].

Figure 6. a) Abdominal CT in acute pancreatitis: Necrotizing pancreatitis (non enhancing parenchyma > 30%) (asterisks), b) More than 50%.

In addition, morphological features of WOPN determine treatment strategy since collections with greater amounts of solid necessitate direct endoscopic necrosectomy as well as aggressive surgical procedures for successful clinical outcome. WOPNs contain both liquid and solid necrotic debris and it is usually difficult to distinguish them from pure liquid collections on contrast-enhanced CT. MRI and endoscopic U/S (EUS) have been shown comparable sensitivity in the detection of the solid necrotic debris. Nevertheless, EUS is an invasive diagnostic modality that causes patient discomfort.

Angiography

Conventional angiography is performed when a pseudoaneurysm is suspected or for the detection of a vascular cause of pancreatitis with regard to polyarteritis nodosum, lupus or vasculitis.

Endoscopic Retrograde Cholangiopancreatography

ERCP is an invasive endoscopic technique which may be useful in the identification of a dilated or normal MPD. Additional communication with a pseudocyst could be acutely elucidated. Moreover, ERCP is warranted for the depiction of a narrowed or tapered distal CBD with prestenotic biliary dilatation.

Differential Diagnosis

- ✓ Infiltrating pancreatic carcinoma
- ✓ Perforated gastric ulcer
- ✓ Trauma
- ✓ Lymphoma and metastases

3. PANCREATIC PSEUDOCYST

Definition

The formation of a pseudocyst refers to a chronic collection of pancreatic fluid surrounded by a nonepithelialized wall of granulation tissue and fibrosis. Pseudocysts occur in up to 10% of patients presenting with acute pancreatitis and 20-38% of chronic pancreatitis affected patients. They may occur intrapancreatically or extend beyond the region of the pancreas into other cavities or compartments.

The lesions may become secondarily infected, in which case they behave as abscesses. They can compress or obstruct adjacent organs or structures, leading to superior mesenteric – portal vein or splenic vein thrombosis. In addition, they can erode into visceral arteries and provoke intracystic hemorrhage or pseudoaneurysm formation [13].

Surgical Interventions

- ✓ Percutaneous drainage of a symptomatic or increase in size pseudocyst
- ✓ Surgical internal (usually into the stomach) or external drainage of a pseudocyst

Imaging Modalities

The role of imaging modalities in case of pancreatic pseudocyst detection is to establish the diagnosis and assess potential necessitation of surgical intervention. Drainage of infected or obstructing pseudocysts is also based on imaging techniques.

If infection is suspected, the pseudocyst should be aspirated by CT- or US-guided FNA, and the contents examined for organisms by Gram's stain and culture. If infection is present, and the contents resemble pus, external drainage is employed, using either surgical or percutaneous techniques.

Finally, although pseudocysts comprise roughly two thirds of all pancreatic cystic lesions, they resemble cystadenomas and cystadenocarcinomas radiographically and therefore differential diagnosis is based on advanced imaging modalities and related diagnostic procedures.

Ultrasound

Real-time U/S usually depicts a solitary unilocular cystic mass at the body or the tail of the pancreas. Multilocular lesions are apparent in 6% of affected patients. Parallel description of fluid-debris level and internal echoes due to autolysis along with blood clots or cellular debris is common U/S finding.

Rarely, septations as well as signs of infection or hemorrhage are defined. Additional dilation of CBD and CPD and calcification of the gland in cases with chronic pancreatitis may be reported.

Computed Tomography

CT characteristic findings of a mature pseudocyst refer to a round or oval, homogeneous, hypodense lesion with a near water density. On the contrary, a hemorrhagic, infected pseudocyst appears as a lobulated, heterogeneous, mixed density lesion. Intense pancreatic calcification as well as MPD and CBD involvement are adequately detected. Enhancement of thin rim of fibrous capsule associated with absence of similar finding of pseudocyst contents is common in contrast-enhanced CT (Figure 7).

The presence of gas within pseudocyst suggests superimposed infection or decompression of pseudocyst into pancreatic duct, stomach or bowel.

Finally, pseudoaneurysms caused by or simulating a pseudocyst could be depicted [14]. Pitfalls in the management of pseudocysts result from the presumptive diagnosis of a cystic neoplasm masquerading as a pseudocyst, a failure to appreciate the solid or debris-filled contents of the lesion which appears fluid filled on CT scan and incompetence to document potential adherence with an adjacent portion of the stomach before attempting transgastric internal drainage. If infection is suspected, the pseudocyst should be aspirated (not drained) by CT- or U/S-guided Fine Needle Aspiration (FNA) and the content examined for organisms by Gram's stain and culture. If infection is identified and the content resembles pus, external drainage is employed using either surgical or percutaneous modalities [15, 16].

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

MR findings are indicative of a hypointense lesion with parallel enhancement of fibrous capsule on T1WI images. On the contrary on T2WI images the pseudocyst presents hyperintense or with mixed intensity containing both fluid and debris.

Figure 7. Abdominal CT: Smooth wall cystic lesions in the lesser sac and the transverse mesocolon (black asterisks). Splenic vein obstruction, gastrosplenic (thick white arrows) and gastric fundus varices.

Subsequent MRCP reveals a hyperintense cyst contiguous with dilated CPD. Similar findings are confirmed on ERCP with the communication of pseudocyst with CPD depicted in 70% of the cases.

Angiography

Conventional angiography is only performed in order to elucidate the diagnosis of pseudoaneurysm. Splenic artery is most frequently involved, followed by inferior and superior pancreaticoduodenal arteries.

Differential Diagnosis

- ✓ Serous microcystic cystadenoma
- ✓ Mucinous cystic tumor of pancreas
- ✓ Intraductal papillary mucinous tumor of the pancreas
- ✓ Cystic islet cell tumor
- ✓ Congenital cysts

4. CHRONIC PANCREATITIS

Definition

Chronic pancreatitis is an incurable, chronic inflammatory condition that is multifactorial in its etiology, highly variable in its presentation, and a challenge to treat successfully. Alcohol consumption and abuse is associated with chronic pancreatitis in up to 70% of cases.

Other major causes worldwide include tropical and idiopathic disease as well as metabolic disorders, hereditary cases and trauma. Radiologic imaging of chronic pancreatitis contributes in four areas including diagnosis, evaluation of severity of the disease, detection of complications and assistance in determining treatment options.

With the advent of cross-sectional imaging techniques such as CT and MRI, the contour, content, ductal pattern, calcifications, calculi and cystic disease of the pancreas are all readily discernible [17, 18].

Surgical Interventions

- ✓ Surgical internal or external drainage of a symptomatic or increase in size pseudocyst
- ✓ Pancreatic duct decompression for chronic obstructive pancreatitis
- ✓ Partial distal pancreatectomy for patients with focal inflammatory changes localized to the body and tail of the gland

- ✓ Radical distal pancreatectomy described by Fry and Child intended for patients with sclerotic small duct disease and preserving the rim of pancreas in the pancreaticoduodenal groove
- ✓ Pancreatoduodenectomy procedure with or without pylorus preservation for symptomatic chronic pancreatitis and pain relief
- ✓ Duodenum-preserving pancreatic head resection described by Beger for the treatment of chronic pancreatitis
- ✓ Extended lateral pancreaticojejunostomy with excavation of the pancreatic head for the complete decompression of the entire pancreatic ductal system described by Frey.

Imaging Modalities

The role of imaging modalities in case of chronic pancreatitis is to establish the diagnosis and differentiate from other conditions which may cause MPD dilatation and glandular atrophy. Additional assessment of potential necessitation of endoscopic or surgical intervention is also imaging dependent. Drainage of infected or obstructing pseudocysts is always based on imaging techniques.

Ultrasound

Transabdominal U/S is frequently employed as an initial imaging method in patients with abdominal symptoms and modifications consistent with pancreatic duct dilatation, intraductal filling defects, cystic changes and heterogeneous texture are encountered in chronic pancreatitis. The sensitivity of transabdominal U/S ranges from 48 to 96% and is operator dependent. Nevertheless, the contour, texture and ductal pattern are usually quite detectable and it is a reliable modality for periodic re-examination to determine the efficacy of therapeutic intervention.

Therefore, major U/S indications of chronic inflammation of the pancreas are the depiction of an atrophic gland along with a tubular anechoic structure consistent with a dilated MPD in up to 90% of the cases and the identification of calcifications appearing as echogenic foci with posterior acoustic shadowing and pseudocyst formation [19].

Computed Tomography

CT scanning has affected diagnostic approach of pancreatic disease more broadly than any other method. Prior to its widespread introduction, pancreatic imaging was largely a matter of detecting the displacement of adjacent, contrast-filled viscera by mass lesions of the pancreas. Since the application of cross-sectional techniques and with the advent of contrast-enhanced CT scanning and CT angiography, visualization of the nature, extent, location and relative relationships of pancreatic structures and lesions is accomplished with great clarity. CT scanning presents a false-negative rate of less than 10% for chronic pancreatitis, but early or mild chronic abnormalities may be undetected [20]. Another drawback of CT scanning is its lower sensitivity for identifying small neoplasms, which may be invisible to all modalities

apart from EUS. Nevertheless, major CT findings indicative of chronic pancreatitis are the presence of an atrophic gland along with an occasionally focal or diffuse enlargement of the pancreas, dilated MPD with ductal calculi, intra and peri-pancreatic cysts formation and extensive thickening of peri-pancreatic fascia (Figure 8).

Additional splenic vein thrombosis implied by splenomegaly and varices confirmation could be depicted. Moreover, a hypodense focal mass with fibrosis and fat necrosis usually in the pancreatic head may simulate neoplastic transformation.

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

MRI, in both the cross-sectional mode and the coronally-oriented heavily weighted T2 or high spin ratio imaging (MRCP) have added heavily to the imaging options of chronic pancreatitis. The resolution of MRI scanning is now approaching that of CT, although its availability and the complexity of the images produced have limited its large-scale use for routine imaging of the pancreas.

A heterogeneous enhancement pattern along with nonenhancing decreased signal areas implying necrosis, and pseudocyst formation usually contiguous with dilated MPD are well depicted. Vascular occlusions may also be demonstrated [21]. Moreover, MRCP has been shown to be an effective screening technique for disclosing ductal abnormalities possessing the advantage of noninvasive methodology and the ability to image obstructed ducts that are not opacified by ERCP injection. Parallel dilatation of MPD with radicles and CBD with smooth distal tapering is the pathognomonic MRCP finding of chronic pancreatitis (Figure 9). Therefore, MRCP remains a useful screening modality to determine duct abnormalities and confirm the need for interventional procedures. Oral, intravenous and intraductal contrast administration are not implemented. Thus, its lack of ionizing radiation makes this imaging technique the safest method to image the ductal system in high-risk patients [22, 23].

Figure 8. Abdominal CT in chronic pancreatitis: Calcification of the pancreatic parenchyma following the course of the main pancreatic duct and its branches (red arrowheads). Mild dilatation of main pancreatic duct and parenchymal atrophy (thick white arrows).

Figure 9. MRCP in chronic pancreatitis: Irregularly dilated main pancreatic duct and its branches (thin blue arrows), communicating (thick red arrow) with a pseudocyst (asterisk).

Endoscopic Ultrasonography

EUS has heavily impacted the evaluation and management of patients with chronic pancreatitis. Although it is more operator dependent and less widely available than transabdominal U/S, EUS provides not only imaging capability, but adds the capacity to obtain cytological and chemical samples of tissue and fluid aspirated with linear array monitor [24, 25]. EUS images obtained through a high-frequency transducer are to evaluate subtle changes in 2- to 3-mm structures within the pancreas, and detect indolent neoplasms in the setting of chronic inflammation. Small intraductal lesions and mucus as well as subtle ductular abnormalities and cystic disorders are also recognizable with EUS [26]. This allows ERCP to be reserved for these patients who require therapeutic maneuvers or for the identification of more problematic nosologic entities (Figure 10). EUS is comparable to ERCP in the detection of advanced changes in chronic pancreatitis and may be more sensitive in the confirmation of mild disease.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

ERCP is considered to be the gold standard for the diagnosis and staging of chronic pancreatitis. It also serves as a vehicle that enables other diagnostic and therapeutic maneuvers such as brushing for cytology or the employment of stents to relieve obstruction or drain a pseudocyst. Dilated and beaded MPD with radicles along with MPD filling defects indicating the presence of intraductal calculi are common ERCP findings of chronic pancreatitis [27]. In addition, CBD may appear dilated with distal narrowing. Unfortunately, ERCP carries a risk of procedure-induced pancreatitis that occurs in approximately 5% of patients. Post-ERCP pancreatitis occurs after uncomplicated procedures as well as after those that require prolonged manipulation. Patients at increased risk include those with documented sphincter of Oddi dysfunction.

Figure 10. EUS in chronic pancreatitis identifying a dilated main pancreatic duct with filling defects indicative of the presence of intraductal calculi.

Therefore, this method should be reserved for patients with unclear diagnosis or in whom a diagnostic and therapeutic intervention is crucial [28].

Differential Diagnosis

- ✓ Pancreatic carcinoma
- ✓ Intraductal papillary mucinous tumor of the pancreas

5. TRAUMATIC PANCREATITIS

Definition

Blunt pancreatic transection at the neck of the pancreas can occur with a direct blow to the abdomen. As an isolated injury it is difficult to detect. Since the MPD is transected the patient will develop a pseudocyst or pancreatic ascites, but there is little inflammation since the pancreatic enzymes remain inactivated. Diagnostic approach can occasionally be accomplished with CT using fine cuts through the pancreas. Nevertheless, CT will not identify a significant number of transections if performed within 6 hours of injury. Optimal management of pancreatic trauma is determined by the location of the injury and whether or not the MPD is involved. In case of an intact MPD treatment may be accomplished only by drainage. In contrast, traumatic pancreatitis associated with a ductal injury always requires therapeutic intervention in order to prevent pancreatic ascites or a major external fistula. Direct exploration of perforations or lacerations will confirm the diagnosis in most instances [29, 30].

Surgical Interventions

- ✓ Surgical drainage in case of pancreatic trauma with an intact MPD
- ✓ Distal pancreatectomy with or without splenectomy for severe injury of the neck, body and tail of the pancreas with parallel MPD transection
- ✓ Limited resection from the site of the injury to the head of the pancreas with preservation of pancreaticoduodenal vessels and CBD in case of severe traumatic lesion of the head and MPD involvement

Imaging Modalities

The role of imaging modalities in case of traumatic pancreatitis is to establish the diagnosis and assess the pancreatic duct integrity. Conservative treatment can also be selected with imaging evaluation at regular intervals.

Ultrasound

Transabdominal U/S findings in traumatic pancreatitis may be similar to those of non-traumatic inflammation of the gland. In addition U/S depiction is not as sensitive and accurate as CT in diagnosing acute injury of the pancreas.

Computed Tomography

Focal or diffuse pancreatic enlargement with irregularity of pancreatic contour is always indicative of traumatic pancreatitis. The presence of edema as well as fluid collection in peri-pancreatic fat with concomitant heterogeneous parenchymal attenuation is often apparent. Thickening of anterior renal fascia may be an additional indirect CT finding. Nevertheless, peri-pancreatic soft tissue changes of traumatic pancreatitis are often subtle and become more evident within 24-48 hours. In case of laceration an area of low attenuation is usually revealed while its actual size is difficult to visualize.

Moreover, potential pancreatic fracture or transection is detected as an ill-defined low density area which results in clear separation of two ends of the gland and nearly always extends through pancreatic neck (Figure 11).

However, lacerations and fractures may produce non-specific changes in parenchymal density and become undetectable on CT scanning. Extra-pancreatic fluid collections around major vascular structures, transverse mesocolon, pararenal space, lesser sac, and the root of mesentery are usually well depicted along with concomitant injury to left lobe of the liver [31]. In conclusion, CT remains the most accurate method of detecting extra-pancreatic fluid collections, pancreatic lacerations or fractures taking into thorough consideration the protocol advice about performing 24-48 hours delayed scans that may uncover findings not present earlier.

Figure 11. Abdominal CT in pancreatic trauma (axial and coronal reformation): Interruption of the pancreatic head (thick white arrow) associated with peripancreatic fluid collection (asterisk).

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

Variable decreased signal intensity with heterogeneous enhancement pattern and non-enhancing hypointense areas indicative of fluid collection, pseudocyst formation and necrosis are often defined in T1W1 images. On the other hand, on fat suppressed T2WI images liquid selections or pseudocysts are demonstrated as hyperintense lesions. Subsequent MRCP reveals possible rupture of MPD (23%) or potential communication with post-traumatic pseudocyst.

Endoscopic Retrograde Cholangiopancreatography (ERCP)

It is obvious based on the above options that no ideal method exists for identifying pancreatic ductal injuries that cannot be ruled out by direct exploration. Alternative method is the use of ERCP. Nevertheless, this modality is very helpful in the delayed diagnosis of a ductal pancreatic injury. Potential transection of MPD reveals an abrupt duct termination or contrast extravasation.

Additional communication of pseudocyst with pancreatic duct may be apparent. However, procedure-induced pancreatitis may also be invoked.

Differential Diagnosis

- ✓ “Shock” pancreas
- ✓ Intramural duodenal hematoma
- ✓ Duodenal rupture

6. SEROUS CYSTADENOMA OF THE PANCREAS

Definition

The term usually refers to a benign glycogen-rich pancreatic tumor that arises from acinar cells with mainly microcystic appearance. It is encountered most frequently incidentally in middle-aged women. Best diagnostic clue is the depiction of a honeycomb or sponge-like mass in pancreatic head with calcification and innumerable small cysts varying from 1-20mm within large cystic lesion.

Tumors show increased frequency in patients with von Hippel-Lindau disease. Based on WHO classification two types of serous cystadenoma are recognized including the microcystic adenoma and the less common oligocystic (macrocystic) variant [32].

Surgical Interventions

- ✓ Complete surgical excision of a symptomatic and large tumor

Imaging Modalities

The role of imaging modalities in cases of serous cystadenoma of the pancreas is to establish the diagnosis and assess whether surgical resection should be implemented.

Differential diagnosis of other cystic tumours categories and pseudocysts is only accomplished on the basis of specific imaging features as well as examination of fluid aspirated under imaging guidance.

Ultrasound

Real-time U/S usually depicts a hyperechoic mass with tiny cystic lesions. Less commonly, a tumor with large cysts defined as discrete anechoic areas with thin walls is described. Additional calcifications are detected as highly reflective echoes with acoustic shadowing.

Computed Tomography

Honeycomb pattern remains the pathognomonic CT finding indicative of a microcystic adenoma. Additional enhancement of septa delineating small cysts or calcification within central scar may be encountered (Figure 12). CBD and/or MPD dilatation as well as atrophy of pancreas distal to the tumor is common among cystic epithelial neoplastic lesions.

Furthermore, macrocystic (usually unilocular) serous cystadenoma is located in the pancreatic head and is depicted with one or few cystic components (locules) covered by thin

non enhancing imperceptible wall. Therefore, differential diagnosis from mucinous cystic lesions remains problematic [33, 34].

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

T1W1 MRI images usually elucidate the presence of a hypointense tumor with central scar enhancement on delayed scan and calcification while blood within cysts is often depicted with varied intensity (Figure 13). Capsular enhancement is also commonly observed. Relevant findings are detected on T2WI images. Subsequent MRCP confirms potential MPD and CBD dilatation. Displacement, narrowing and dilatation of adjacent MPD and/or CBD are also mentioned in ERCP.

Figure 12. Abdominal CT showing a multicystic lesion that contains tiny cysts and central calcification at the pancreatic tail (thick white arrow).

Figure 13. Abdominal MRI a) MRCP: Multicystic pancreatic lesion containing various sized cysts b) T2W image: Multicystic lesion with central scar (red asterisk).

Angiography

Conventional angiography reveals a highly vascular tumor due to extensive capillary network within septa with neovascularity and dense blush. Large cysts produce lucent regions with dilated feeding arteries and prominent draining veins.

Nevertheless, exclusive angiographic characteristics are absent.

Endoscopic Ultrasonography

The unequivocal diagnosis of a pancreatic cystic lesion without a clear association to acute or chronic pancreatitis should always raise a tumor suspicion, reinforced by other factors such as female gender, higher age and location in the gland. Among the tumors, the mucinous types have to be taken more seriously with surgery being considered in all of them, whereas the rate of malignancy in serous cystadenomas seems to be very low [35, 36]. Early papers suggested specific EUS image features to be more frequent among different types of cystic tumors, but this may not be helpful in the individual case (Figure 14).

Furthermore, agreement among endosonographers was only fair in this differential diagnosis. It is assumed that the risk of malignancy is very low for serous cystadenoma, which was confirmed recently in a series of 158 such cases undergoing surgery, with only two malignancies, one diagnosed initially, the other one on follow-up due to metastases after an initial benign diagnosis from the resection specimen.

Figure 14. EUS depiction of serous cystadenoma of the pancreas with multiple small compartments within a cystic mass (honeycomb appearance).

Studies evaluating EUS-FNA with different parameters to be assessed from the aspirated fluid (amylase, mucin, CEA, cytology) also reached contradictory conclusions [37]. EUS potentially with FNA in general contributes limited information to the management of patients with indeterminate cystic lesions.

Clinical parameters including absence of pancreatitis, gender and age add at least as much important information as morphology (EUS and/or CT) and FNA results do. Surgery should be considered in all operable patients with incidental cysts located at the head of the gland. Specific parameters with regard to morphology suggesting serous cystadenoma may lead to FNA in individual cases, if the results have an impact on the patient's management.

Differential Diagnosis

- ✓ Mucinous cystadenoma of pancreas
- ✓ Intraductal papillary mucinous tumor (IPMT)
- ✓ Pseudocyst
- ✓ Pancreatic carcinoma
- ✓ Congenital pancreatic cysts
- ✓ Cystic islet cell tumor

7. MUCINOUS CYSTIC PANCREATIC TUMOR (MCPT)

Definition

The terminology refers to an uncommon primary enhancing multiseptated mass in the body or tail of the pancreas. It is recognized as a large smooth encapsulated lesion with thick fibrous capsule and lobulated surface.

The presence of multi-/unilocular large cysts is obvious. Cystic cavity may be filled with thick mucoid material or clear, green blood-tinged fluid. Otherwise, solid papillary projections protrude into interior of the tumor indicating the malignant potential of the neoplasm which shares both clinical and pathologic characteristics of biliary and ovarian tumors.

Rarely MCPT may manifest with local invasion or distant metastases or symptoms of mass effect on adjacent structures. Laboratory data including increased levels of serum CEA and elevated cyst fluid levels of CA 19-9 and CA 72-4 present 80% sensitivity and 95% specificity for tumor identification [38].

Surgical Interventions

- ✓ Complete surgical excision

Imaging Modalities

The role of imaging modalities in case of mucinous cystic pancreatic tumor is to establish the diagnosis and confirm the need for subsequent complete surgical resection. Differential diagnosis of other cystic tumours categories and pseudocysts is only accomplished on the basis of specific imaging features as well as estimation of fluid aspirated with image-guided diagnostic procedures.

Ultrasound

Real Time U/S usually detects a multilocular cystic mass with echogenic internal septa. Alternatively, a unilocular anechoic lesion is frequently depicted with limited contribution to the differential diagnosis among cystic pancreatic neoplastic disorders.

Computed Tomography

NECT reveals a hypodense unilocular or multilocular cyst with focal calcifications.

Subsequent CECT describes a multilocular cystic lesion with enhancement of thin internal septa and cyst wall [39].

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

On T1W1 images variable signal intensity based on cyst content is documented. Fluid-like material as well as focal calcifications are characterized as hypointense while proteinaceous or hemorrhagic elements are hyperintense.

On the other hand, cystic lesions are depicted as hyperintense areas with hypointense internal septations and focal calcifications on T2WI images (Figure 15).

MRCP as well as ERCP is indicative of extensive displacement, narrowing and prestenotic dilatation of MPD adjacent to tumor [40].

Angiography

Conventional angiography often reveals a predominantly avascular cystic mass with solid components and small areas of vascular blush and neovascularity. Additional displacement of surrounding major vascular structures is identified.

Figure 15. Abdominal MRI of a mucinous pancreatic tumor: a) T2W image: Unilocular cystic lesion with hypointense mural nodule (black asterisk) b) 3D T1 fat suppressed image: Hyperintensity of the cystic content indicating the presence of mucin (black asterisk) c) 3D T1 fat suppressed image after contrast medium administration: Enhancement of the mural nodule (red thick arrow).

Endoscopic Ultrasonography

Several EUS findings have been evaluated to diagnose pancreatic cystic lesions. Small cyst size does not exclude malignancy; one series reported 20% of lesions 2cm or smaller to be malignant and 45% possessed malignant potential.

However, only 3.5% among asymptomatic lesions with tumor size less than 2cm were malignant [41]. Certain features do appear to be more predictive in diagnosing particular types of cystic pancreatic lesions (Figure 16, 17). The finding of multiple small compartments within a cystic mass is suggestive of a serous cystadenoma, with an accuracy of 92% to 96%, and is not encountered in mucinous cystadenomas [42].

In addition, a cystic tumor without septations or solid components and detected within a pancreas having parenchymal abnormalities suggests a pseudocyst formation with a sensitivity of 94% and a specificity of 85%.

EUS findings may also help identify those patients with mucinous lesions with malignant potential who might benefit from surgical resection. One study reported that the presence of any one of the following had a sensitivity of 91% but a specificity of 60% for detecting a lesion with malignant potential: (1) cyst-wall thickness greater than 3mm, (2) intracystic compartments larger than 10mm (“macroseptations”), (3) intramural masses, or (4) cystic dilatation of the MPD [43]. Another study found the accuracy for detecting those lesions with malignant potential varied from 40% to 93%.

This suggests that, whereas EUS findings may add some diagnostic information, results may not be reliable enough for making management decisions [44].

Figure 16. EUS showing a mucinous cystic tumor of the tail of the pancreas with characteristic cyst-wall thickness.

Differential Diagnosis

- ✓ Serous cystadenoma of the pancreas
- ✓ Intraductal papillary mucinous tumor (IPMT)
- ✓ Pseudocyst
- ✓ Variant of ductal adenocarcinoma
- ✓ Congenital pancreatic cysts
- ✓ Cystic islet cell tumor
- ✓ Lymphangioma

8. INTRADUCTAL PAPILLARY MUCINOUS TUMOR

Definition

IPMT is a subdivision of mucin producing tumors along with mucinous macrocystic neoplasm and is classified into three types:

- Branch pancreatic duct (BPD) type with focal lobulated "multicystic" dilatation of branch ducts
- Main pancreatic duct (MPD) type with diffuse dilatation of MPD
- Combined type with parallel dilatation of both BPD and MPD which is the most common variety.

Figure 17. EUS showing a mucinous cystic tumor of the pancreas with intracystic compartments, intramural masses and associated cystic dilatation of the main pancreatic duct.

Tumors are typically papillary lesions ranging in size from a few millimeters to panductal with varying proportions of dysplasia and in situ cancer. Papillary projections protrude into and expand BPD and MPD as well. Excessive mucin production combined with obstruction and dilatation of BPD and MPD is also noted. Most specific predictive signs of malignant transformation refer to diabetes mellitus, detection of a solid mass on imaging or a dilated MPD more than 10mm, diffuse or multifocal involvement and presence of attenuating or calcified intraluminal content. Associated laboratory data refer to increased serum and urinary amylase and altered pancreatic function tests [45].

Surgical Interventions

- ✓ Laparoscopic distal pancreatectomy with or without splenic preservation may be employed for cystic lesions located in the tail of the pancreas
- ✓ Duodenum-preserving pancreatic head resection for isolated lesions in the head of the pancreas
- ✓ Total pancreatectomy in case of multi-focal disease

Imaging Modalities

The role of imaging modalities in case of intraductal papillary mucinous cystic tumor of the pancreas is to establish the diagnosis and confirm the necessity of concomitant complete surgical excision.

Differential diagnosis of other cystic tumours categories and pseudocysts is only accomplished on the basis of specific imaging features as well as estimation of fluid aspirated with advanced imaging guided diagnostic procedures.

Therefore, imaging methods potentially with FNA contributes significant information to the management of patients with indeterminate cystic lesions of the pancreas.

Ultrasound

Real-time U/S usually defines the presence of a septated cystic lesion along with a dilated MPD and occasionally punctate calcifications. Nevertheless, intra-operative or endoscopic sonography affords superior visualization of ductal system of the pancreas.

Computed Tomography

Differential diagnosis among pancreatic cystic lesions as well as specific types of IPMTs is always attempted with CECT scanning. BPD type is described as a thin, lobulated, irregular, peripheral ring-enhancing "multicystic" lesion.

A bulging ampulla at duodenal sweep with thin rim enhancement is often apparent [46]. On the contrary, MPD type is related to a markedly dilated tortuous MPD. Additional punctate calcifications along with polypoid lesions lining MPD may be visualized.

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

On axial T1WI images hypointense branch duct cysts associated with a dilated MPD are always revealed. In addition, clustered cystic lesions with thin septa are depicted on coronal T1W1 images. On T2WI depictions relevant disorders are hyperintense with parallel detection of papillary excrescence in cystic lesion of pancreatic head or along MPD.

Subsequent MRCP is mainly indicative of lobulated clustered cysts, dilated MPD and possible communication between cystic tumors and ductal system (Figure 18). Intraductal mucin and papillary lesions may be also described as nodular filling defects [47].

Figure 18. Intraductal papillary mucinous tumor of the pancreas a) Abdominal CT: Irregular dilatation of the main pancreatic duct with associated cystic branches dilatation b) MRCP: Large cystic lesion at the pancreatic head (black asterisk), cystic dilatation of main pancreatic duct and its branches c) 3D T1 Fat Suppressed image after contrast medium administration: Enhancement of the solid component of the cystic lesion, indicating malignant transformation (green arrow).

Endoscopic Retrograde Cholangiopanceatography

ERCP confirms the diagnosis of IPMT of pancreas contributing to the detection of a dilated MPD with thick intraductal mucinous secretions. Mucin and papillary tumors are clearly defined as elongated, nodular or band-like filling defects in MPD. Concomitant real-time visualization of patulous ampulla and increased mucus production is warranted.

Endoscopic Ultrasonography

EUS cannot accurately determine the extent of involvement of IPMT and is not reliable in distinguishing malignant from benign forms of this neoplasm (Figure 19).

Intraductal U/S may suggest malignant IPMT by the presence of protruding lesions ≥ 4 mm (Figure 20). Areas of uncertainty likely reflect the only fair to moderate agreement among experienced endosonographers about the presence or absence of particular EUS findings or specific diagnoses [48, 49]. EUS-guided FNA (EUS-FNA) of pancreatic cystic lesions yields fluid for cytological and chemical analyses.

Moreover, any solid components associated with a lesion or regional lymph nodes can be aspirated for cytology or histological evaluation. Dilated pancreatic ducts can be safely targeted for FNA when IPMT is suspected. Knowledge of patient's clinical history may help improve the accuracy of EUS for diagnosing IPMTs [50].

Differential Diagnosis

- ✓ Serous cystadenoma of the pancreas
- ✓ Mucinous cystic neoplasm
- ✓ Pancreatic pseudocyst
- ✓ Pancreatic carcinoma
- ✓ Chronic pancreatitis

Figure 19. EUS detection of double duct sign associated with main branch intraductal papillary mucinous tumor of the pancreas.

Figure 20. EUS detection of a dilated main pancreatic duct with thick intraductal mucinous secretions indicative of the presence of intraductal papillary mucinous tumor of the pancreas.

9. PANCREATIC DUCTAL CARCINOMA

Definition

Pancreatic adenocarcinoma is the most common type of pancreatic cancer accounting for more than 80% of all pancreatic malignancies. About two thirds of pancreatic adenocarcinomas arise within the head or uncinate process of the pancreas; 15% are located in the body, and 10% in the tail, with the remaining tumors demonstrating diffuse involvement of the gland [51]. Tumors in the pancreatic body and tail are generally larger at the time of diagnosis, and therefore, less commonly resectable.

Tumors in the head of the pancreas are typically diagnosed earlier because they cause obstructive jaundice. Ampullary carcinomas, carcinomas of the distal bile duct, and periampullary duodenal adenocarcinomas present in a similar fashion to pancreatic head cancer but possess a slightly better prognosis, probably because early obstruction of the bile duct and jaundice leads to the prompt diagnosis. Exact pathologic staging of pancreatic cancer is important because it allows accurate quantitative assessment of results and comparisons between institutions. Surgery with margin negative resection also known as R0 resection is the only potentially curative approach in pancreatic carcinoma.

However, only 15-20% of affected patients present with potentially resectable disease. Due to the high morbidity of the surgical procedure, accurate selection of patients in the preoperative setting who will proceed to operation is critical [52].

Surgical Interventions

- ✓ Distal pancreatectomy with splenectomy may be employed for pancreatic adenocarcinomas located in the body and the tail of the gland
- ✓ Pancreaticoduodenectomy, also called “Whipple operation,” for complete resection of isolated malignant lesions in the head of the pancreas
- ✓ Palliative endoscopic stenting for obstructive jaundice relief
- ✓ Palliative gastric by-pass in case of duodenal obstruction of unresectable tumor
- ✓ Palliative celiac nerve block for abdominal pain

Imaging Modalities

The role of imaging modalities in cases of pancreatic ductal carcinoma is to establish the diagnosis and assess tumor resectability. The accuracy of imaging techniques for predicting unresectable disease is about 90 to 95%.

Specific imaging findings that indicate a tumor is unresectable include invasion of the CHA or SMA, enlarged lymph nodes outside the boundaries of resection, ascites, and distant metastases mainly to the liver. Invasion of the SMV or PV remain relative contraindications to resection as long as the veins are patent.

Ultrasound

One of the common presentations of patients with pancreatic adenocarcinomas of the head of the pancreas is painless jaundice. The initial imaging modality is typically an ultrasound to evaluate the intrahepatic biliary system, the common duct and the gallbladder.

Presence of CBD dilatation along with intrahepatic and MPD involvement is a strong indication for further meticulous investigation with cross sectional imaging. Real-time U/S often reveals a hypoechoic mass combined with contour deformity of the gland. Due to overlying bowel gas and differences in operator scanning technique and experience, U/S is not typically used as the modality of choice in staging pancreatic adenocarcinoma.

Computed Tomography

CT is usually the cross sectional imaging modality of choice for staging in pancreatic cancer patients. Parallel administration of oral and iodinated contrast intravenously injected prior to the CT scan is implemented. Dual phase imaging is performed. The first phase refers to the pancreatic parenchymal process of enhancement while the second one describes the portal venous phase. The pancreatic tumor is best detected during the first phase of enhancement due to optimal depiction of the pancreas with greatest attenuation difference between the tumor and the normal gland (Figure 21).

Liver metastatic disease is best elucidated in the second portal phase of enhancement. The images are reconstructed at either 0.625 or 1.25mm slice thickness. These thin section images can help in multiplanar reconstructions and in improved detection of small tumors. Associated secondary signs of malignancy as well as potential vascular involvement are always assessed. Pancreatic adenocarcinomas are typically low attenuation, infiltrative masses on the pancreatic parenchymal phase of enhancement.

Figure 21. Abdominal CT in pancreatic ductal carcinoma: a) Pancreatic phase of enhancement: Small pancreatic cancer causing obstruction of the common bile duct and the main pancreatic duct (red arrow) b) Portal phase of enhancement: The pancreatic lesion is not visible.

Figure 22. Abdominal CT in pancreatic ductal carcinoma: Pancreatic phase of enhancement, curved reconstruction along the course of MPD: Hypoattenuating lesion (pancreatic cancer) obstructing the main pancreatic duct (white arrow), causing upstream dilatation and distal atrophic changes.

Secondary signs of malignancy include loss of normal lobulation of the pancreatic parenchyma along with CBD and MPD narrowing or obstruction with upstream dilatation and distal pancreatic atrophic changes (Figure 22) [53, 54].

Vascular involvement may be related to venous or arterial infiltration. The most commonly affected veins are the SMV, portal and splenic vein respectively depending on the primary tumor location (Figure 23). The most commonly involved arteries can include the GDA, SMA, inferior pancreaticoduodenal artery (IPDA), splenic artery, CHA and celiac trunk as well. The T3 stage refers to extension of the tumor outside the pancreas with respect to the celiac trunk or the SMA.

On the contrary, T4 stage suggests involvement of relevant vascular structures (Figure 24). The location of the pancreatic tumor determines its local spread and potential infiltration of major vessels. Gradual development of pancreatic tail lesions often involves the splenic vessels and the splenorenal ligament (Figure 25).

Moreover, a tumor that is located in the body of the pancreas may spread to involve the celiac trunk and its branches. A body tumor if large enough can extend caudally to involve the SMA. A tumor located in the anterior head and neck of the pancreas may spread to involve the GDA, CHA and the gastroduodenal trunk respectively. A tumor of the posterior neck and head of the pancreas typically can involve the PV as well as the portal venous confluence, the SMV and the SMA.

Finally, an uncinate tumor tends to typically track along the IPDA and may secondarily involve the jejunal and the mesenteric vessels [55].

A relatively new category is emerging from pancreatic cancer staging called “borderline resectable” tumors. The amount of extension or involvement of the celiac artery or SMA can vary on CT evaluation [56]. The term “abutment or involvement” has been designated to correspond to extension of tumors that involve less than 180° of the circumference of the vessel while the term “encasement” has been proposed to refer to development of the tumor more than 180° of the circumference of the vessel.

Figure 23. Abdominal CT in pancreatic ductal carcinoma: Portal phase of enhancement coronal reconstruction: Pancreatic neck cancer invading the splenomesenteric confluence and the proximal portal vein (thick blue arrow).

Figure 24. Abdominal CT in pancreatic ductal carcinoma: Pancreatic phase of enhancement: a) Pancreatic tumor encasing the superior mesenteric artery (white asterisk) b) Encasing of the superior mesenteric vein and the splenomesenteric confluence (black asterisk).

Figure 25. Abdominal CT in pancreatic ductal carcinoma: Pancreatic phase of enhancement: Inhomogeneous necrotic lesion at the pancreatic tail (blue circle), invading the perirenal fascia (white arrows).

Borderline resectable tumors are defined as lesions that abut or encase a short segment of the common hepatic artery without involvement of the celiac artery, abut the SMA or may cause short segment occlusion of the SMV, PV or the portal venous confluence with suitable veins above and below the level of the occlusion for venous reconstruction (Figure 26).

The importance of the borderline resectable category is that affected patients appear with CT findings that preclude immediate surgery due to high risk for a margin positive resection [57]. These patients are typically treated with neoadjuvant chemotherapy or combined chemoradiation therapy. Advantages of neoadjuvant chemoradiation include optimal patient selection for surgical intervention by excluding those patients with progressive disease on therapy and by initiating immediate treatment to prevent systemic spread.

Recently defined CT criteria for vascular involvement in pancreatic adenocarcinoma in comparison with surgical results confirm that identification of fat plane (type A) or normal pancreatic parenchyma (type B) separating the tumor from adjacent vessels predict tumor resectability in 95% of selected patients. When the tumor is inseparable from the vessels but the points of contact form a convexity against the vascular structure (type C), CT is not reliable in predicting vascular involvement.

When the tumor is partially encircling (type D) the vessel, the tumor is fixed against the vessels in the majority of the cases. Forty seven percent of these patients are resectable but relevant procedure usually involves venous resection as well.

When the tumor is completely encircling (type E) or occluding (type F) the vessel, 100% of the lesions could not be resected with a negative margin. This yielded a sensitivity of 84% and a specificity of 98% [55].

Detailed anatomy of the peripancreatic lymph nodes was originally described by the Japanese Pancreatic Society. The T, N, and M categories all independently influence survival of pancreatic carcinoma [58]. Nevertheless, nodal involvement has been reported the strongest predictor of poor survival after pancreatic resection for invasive pancreatic adenocarcinoma. The presence of GDA node positivity shares a poor prognosis similar to that of metastatic disease spread to the peritoneum or liver. The incidence of nodal involvement is 72-83% on autopsy series [59].

Figure 26. Abdominal CT in pancreatic ductal carcinoma: Abdominal CT: a) Portal phase of enhancement: Pancreatic tumor abutting the superior mesenteric artery, tear drop sign of the superior mesenteric vein (thick white arrow) b) Pancreatic phase of enhancement sagittal reformation: Pancreatic tumor abutting the superior mesenteric artery (thin white arrows).

CT accuracy for nodal staging is 44-47% after meticulous correlation of imaging findings with pathology results. In addition, detection of ovoid nodal shape, clustering of nodes and the absence of a fatty hilum are not useful predictors of malignancy on CT [60]. Moreover, the incidence of con-peritoneal involvement is between 40-55%. While the most common CT finding is that of peritoneal thickening, small nodules and ascites, larger peritoneal implants and omental caking may be encountered. Additional liver metastases are typically low attenuation lesions and may present perilesional enhancement on the pancreatic parenchymal phase, which fades on the portal phase of enhancement.

Nevertheless, detection of small volume liver metastases and peritoneal implants remains challenging despite the use of CT in the preoperative staging of pancreatic adenocarcinoma [61, 62]. Finally, the most common appearance of pulmonary metastases is lung nodules with irregular or speculated borders. However, lung metastases with a diffuse air space pattern or with lymphangitic carcinomatosis may be recognized [63].

Magnetic Resonance Imaging – Magnetic Resonance Cholangiopancreatography

Pancreatic ductal adenocarcinoma typically manifests as an infiltrating poorly defined mass, desmoplastic in nature, with sparse vascularity. This histology contrasts with that of normal pancreatic parenchyma. For this reason, small tumors are well seen as relatively low signal intensity poorly defined lesions on fat suppressed T1 weighted images against the normal high signal intensity of uninvolved pancreatic parenchyma (Figure 27) [64].

Figure 27. Abdominal MRI demonstrating a small pancreatic ductal carcinoma: a) MRCP: Obstruction of the common bile duct with proximal dilatation of the biliary ducts b) Diffusion Weighted Image: Hyperintense lesion (restricted diffusion pattern) at the pancreatic head (thick white arrow) c) 3D T1 Fat Suppressed image: Hypointense lesion at the pancreatic head (thick white arrow).

Pancreatic cancer is most conspicuous on the arterial phase of dynamic gadolinium imaging against the prominently enhancing capillary rich uninvolved surrounding pancreatic parenchyma. Close attention to technique, particularly timing, is vital [65].

On delayed, interstitial phase images, the appearance of pancreatic cancer can be very variable. Small pancreatic tumors can present a variable enhancement pattern, ranging from hypointense to slightly hyperintense on delayed images and may actually show rim enhancement. In contrast, large pancreatic ductal adenocarcinomas tend to remain low in signal intensity on delayed images [66].

Often pancreatic tissue proximal to pancreatic cancer may be lower in signal intensity than the normal gland. This typically occurs as a consequence of tumor associated pancreatitis secondary to the obstruction of the MPD. The greater the resultant progression to fibrosis and glandular atrophy from long standing pancreatic ductal obstruction, the less conspicuous the pancreatic carcinoma. For this reason, all sequences must be carefully evaluated to define the true extent of the tumor. The combined MRI features of a focal pancreatic mass, pancreatic duct dilatation and parenchymal atrophy are highly suggestive of ductal adenocarcinoma. However, it should be noted that it may be impossible to accurately differentiate pancreatic adenocarcinoma from focal chronic pancreatitis [67]. Comparing MR imaging with CT, several studies suggest that MRI is comparable to the detection and staging of pancreatic cancer. Recent meta-analysis of 68 studies revealed the sensitivity of MRI to be 84% versus 91% for helical CT in the evaluation of pancreatic adenocarcinoma. The sensitivity to resectability was equal for both MR and helical CT (82 and 81%). It has been suggested that due to MRI's inherently higher soft tissue contrast, the recognition of subtle pancreatic lesions could be potentially improved over CT [68].

Because of the heavily T2 weighted nature of MRCP imaging, what is visualized on this diagnostic modality is the effect of tumor on a fluid filled duct. The lesion itself is not commonly seen. For this reason, a comprehensive workup of a pancreatic mass typically includes additional sequences including dynamically enhanced imaging. The double duct sign indicating the obstruction of both the CBD and the MPD was described initially on ERCP, but this sign can also be identified with other modalities such as MRCP. More commonly depicted are ductal stenoses or associated obstruction. Nevertheless, although the double duct sign, when confirmed at MRCP, is highly suggestive of pancreatic head malignancy, it is not pathognomonic [69]. On MRCP, the "duct penetrating sign" has been suggested as a means to distinguish an inflammatory pancreatic mass from pancreatic carcinoma.

This sign is encountered in 85% of chronic pancreatitis and only 4% of patients with cancer and refers to the visualization of the MPD penetrating an inflammatory pancreatic mass rather than the complete obstruction seen commonly with pancreatic carcinoma (Figure 28) [64]. Some studies have reported the specificity of this sign being as high as 100% for benign stricture. Therefore, it has been suggested that MRCP may provide a benefit in differentiating benign lesions from malignancy [70]. Another important factor to consider is that seeing a normal sized pancreatic duct on MRCP in the setting of extrahepatic biliary obstruction should not be interpreted as excluding the possibility of pancreatic carcinoma. Indeed, it has been reported that the caliber of the MPD can be normal in up to 20% of patients with pancreatic malignancy causing bile duct obstruction. Finally, when MRCP is used in combination with a dynamic MR examination of the pancreas, comprehensive preoperative imaging can be accomplished to facilitate the detection and preoperative staging of a pancreatic cancer.

Meticulous evaluation of the combined use of MRI and MRCP in the diagnostic procedures of pancreatic neoplastic disease showed a sensitivity of 87%, a specificity of 97%, and an accuracy of 95% [71]. It is also important to note that the isolated obstruction of the pancreatic duct, even in the absence of a pancreatic mass, should be viewed with great suspicion for the possibility of an underlying tumor. Accurate staging is of particular importance for pancreatic cancer because of the aggressive nature of the disease.

Overstaging can prevent patients from potentially curative surgical intervention. On the contrary, understaging can subject patients to unnecessary morbidity from futile surgery. Complete surgical resection is only possible in the absence of metastatic disease and in those patients in whom the tumor can be removed in its entirety with negative surgical margins (R0 resection) [72]. Patients with locally advanced ductal adenocarcinoma of the pancreas subjected to surgery with macroscopic positive margins (R2 resection) have no survival benefit over those who receive palliative care.

Therefore, accurate pretreatment staging is crucial to correctly identify surgical candidates and differentiate them from patients with unresectable disease [73]. Recent advances in surgical technique with venous interposition grafts has impacted on patients previously considered with unresectable disease and moved them into the potentially resectable category. Advances in chemotherapy, surgery, and radiation, including protocols of combined preoperative therapeutic approach, can potentially result in downstaging of patients with previously unresectable tumors. The demand for accurate preoperative evaluation of treatment planning has placed added responsibility on radiology to precisely assess the local extent of disease. Furthermore, in those patients who are considered resectable, imaging is also expected to provide an accurate roadmap in order to facilitate surgical planning.

Accurate preoperative staging of pancreatic cancer requires a careful evaluation of tumor infiltration into the major peripancreatic arteries. The same principles and grading system have been applied in the literature to contrast enhanced CT and MRI [74].

Most studies have shown MRI to be comparable to CT regarding the accuracy of staging. Early investigations comparing MRI with helical CT showed MRI to be equal to, or even possibly slightly better than, helical CT.

Figure 28. Abdominal MRI: a) MRCP, b) T2W image: Irregular dilatation with segmental stenoses of the main pancreatic duct, penetrating a solid lesion (black asterisk) at the pancreatic head with concomitant dilatation of the common bile duct (thin white arrows). This is a penetrating duct sign in a case of focal pancreatitis.

Recently, with the major advance of multidetector CT (MDCT) technology, which continues to evolve, the difference between MRI and CT has narrowed. In the past, the involvement of the PV or SMV was considered a contraindication to surgery. However, with the development of venous bypass grafts, venous involvement is no longer considered necessarily unresectable disease, but this is not necessarily the case at all institutions [75]. Careful description by radiologists of the extent of venous involvement is therefore necessary for surgical planning. The signs of venous vascular invasion are similar on both CT and MR imaging and refer to occlusion, deformity of the vascular contour including “beaking” and tumor vessel contiguity greater than half the circumference of the vessel.

With recent advances in surgical technique, particularly in venous resection and reconstruction with interposition venous grafts, tumor involvement limited to the PV or SMV can be considered for potentially curative resection. It is now possible in certain institutions to resect and reconstruct the SMV and PV as long as the vessel remains patent with normal flow and adequate distal (PV) and proximal (SMV) margins free of tumor can be obtained [76]. Vascular encasement is best demonstrated on MR imaging with contrast enhanced 3D spoiled gradient echo images with thin sections, which may be reviewed in the axial plane or reconstructed in the coronal or sagittal planes. Coronal and sagittal reconstructions may be of value to illustrate the length of tumor involvement of the vessel in question as this information has important implications for surgical planning [77].

In certain institutions, long segment (more than 2cm) encasement or occlusion of the SMV or PV is a relative contraindication to vascular reconstructive surgery, although the boundaries of resectable disease appear to be continually changing. In addition, attention to variant venous anatomy is now important, and certain anatomic variations may render venous reconstructions difficult or even impossible. As an illustration, multiple jejunal branches inserting high on the SMV near the PV may preclude an adequate proximal surgical margin for an interpositioned venous graft.

It is important to note that the location of the pancreatic tumor determines the primary route of spread and the regional nodal groups involved. The secondary drainage usually describes the nodal stations in the porta hepatis, celiac axis, and nodes along the root of the small bowel mesentery. The para-aortic nodal stations represent third order lymphatic drainage and are considered distant nodal metastases. Cross sectional imaging modalities such as CT and MRI traditionally rely on size to discriminate between normal and metastatic lymph nodes, and therefore both techniques suffer from poor sensitivity and specificity for the detection of nodal metastases. The high prevalence of nodal micrometastases in pancreatic cancer makes nodal enlargement a poor predictor of nodal involvement. Using a criterion of greater than 1cm in short axis diameter for metastatic nodes on helical CT yields a sensitivity of only 14%, specificity of 85%, positive predictive value (PPV) of 17%, and negative predictive value (NPV) of 82% [78]. Another confounding factor is that of superimposed inflammatory changes. Pancreatitis can complicate the diagnosis of pancreatic cancer, particularly, following invasive diagnostic procedures such as ERCP. The inflammatory changes may result in reactive peripancreatic lymphadenopathy, contributing to an overall low staging accuracy for CT and MRI.

On MRI, lymph nodes are well demonstrated on T2 weighted sequences with fat suppression and interstitial phase gadolinium enhanced fat suppressed images. Lymph nodes appear as well defined moderately hyperintense oval masses against a background of low signal intensity with both techniques.

On T1 weighted images without fat saturation lymph nodes appear as low signal intensity oval masses in a background of high signal intensity fat. Imaging in the coronal plane may be helpful for the identification of mesenteric and peripancreatic nodes.

Pancreatic cancer frequently metastasizes to the liver and the detection and the characterization of hepatic lesions in the setting of pancreatic malignancy are of paramount importance and are achieved through differences in signal intensity between the metastatic implants and the adjacent liver parenchyma. High sensitivity for lesion assessment and specificity for lesion characterization are achieved by selecting the appropriate imaging protocol consisting of T2 weighted sequences, T1 weighted gradient echo images pre-contrast, and dynamic gadolinium enhanced gradient echo images with fat suppression. Most hepatic metastases are of lower signal than the surrounding hepatic parenchyma on T1 weighted sequences, which is in contradistinction to lesions of hepatocellular origin, such as focal nodular hyperplasia (FNH) or well differentiated hepatocellular carcinoma (HCC), which appear isointense to normal liver.

Furthermore, T1 weighted gradient echo in and out of phase sequences are very helpful to demonstrate focal fatty infiltration and sparing as well. These entities are known to decrease lesion conspicuity on CT, contributing to the lower sensitivity of this imaging modality for lesion detection in the setting of hepatic steatosis. T2 weighted sequences possess higher sensitivity to hepatic metastases than unenhanced T1 weighted images. Metastases usually appear as focal areas of moderately high signal on T2 weighted images in comparison with the remainder of the hepatic parenchyma.

Moreover, a broad range of MR imaging sequences and MR specific contrast agents is available to detect and characterize liver lesions. Finally, the appearance of peritoneal metastases on MR imaging ranges from small well demarcated nodules to diffuse thickening of the peritoneal lining, both of which usually show enhancement on T1 weighted fat suppressed sequences. The detection of small peritoneal nodules on cross sectional imaging involves a meticulous evaluation of the peritoneal cavity and its many recesses. Several studies have shown that dynamic contrast enhanced MR imaging is equal to or superior to contrast enhanced CT for the detection of peritoneal metastases [79].

Positron Emission Tomography

Currently CT is the modality of choice for diagnosing and staging pancreatic adenocarcinoma, because of its better spatial resolution and the ability to generate 3D images and multiplanar reformations. However, sometimes it is difficult to differentiate mass forming chronic pancreatitis, post treatment fibrosis from pancreatic adenocarcinoma and tumors less than 2cm in diameter [80].

Therefore, the utility of PET imaging is being explored to overcome some of these limitations. PET is an imaging technique that provides exclusive information about the molecular and metabolic changes associated with disease. The last years, remarkable improvements in technology, the routine availability of medical cyclotrons (to produce the necessary short lived positron emitters), and favorable reimbursement decisions have led to an increase in the use of this technology. The currently available agent for clinical use in published reports to evaluate pancreatic cancer with PET is the FDG. PET is a noninvasive method of tissue characterization based on specific tissue metabolism.

There are a few other investigational radiotracers available to image pancreatic cancer such as (18)F fluorothymidine (FLT) PET/CT, 11C harmine (a MAO A inhibitor) and (11C) acetate as well [81, 82].

In 1956, Warburg described that, malignant cells demonstrated increased glucose consumption. This high glycolytic rate in malignant cells forms the basis of PET imaging. Several early comparative studies have shown FDG PET to be more accurate than conventional imaging techniques in diagnosing pancreatic carcinoma [83]. However, more recent surveys have shown that the role of FDGPET is still very controversial and suggest that there may be a complementary role of FDG PET to conventional CT imaging. A well-documented meta-analysis demonstrated that in the 387 patients studied, the weighted average sensitivity and specificity of FDG PET were 94 and 90% respectively compared with 82 and 75% for CT [84]. Nevertheless, a more recent investigation elucidates that FDG PET presents a lower sensitivity than CT and does not add additional information to the contrast enhanced CT. Therefore, FDG PET is helpful in the diagnostic approach of patients in whom CT does not identify a mass and in detection of metastatic disease [85].

Due to the high quality of cross sectional imaging, increasing number of patients are being diagnosed with cystic lesions the pancreas. However the conventional imaging techniques are limited in their ability to confidently distinguish benign from malignant cystic neoplasms. The presence of mural nodularity, internal septations, wall thickening and calcification is considered a predictor of malignancy on CT depiction. The presence of focal FDG activity within these lesions, irrespective of lesion morphology therefore provides a significant advantage to detect malignancy [86]. The importance of this finding lies in the fact that when FDG PET is used in the proper clinical setting of asymptomatic and high risk patients, lack of activity within a known cystic mass can reliably exclude malignancy and may help prevent unnecessary surgery.

Due to its low spatial resolution, FDG PET has a limited role in the T staging of pancreatic cancer. The extent of the tumor into the peripancreatic tissues and the adjacent vessels cannot be outlined. Therefore, conventional cross sectional imaging modalities, particularly multiphasic contrast enhanced multi detector helical CT and MRI can better demonstrate the relationship between the tumor, the adjacent organs, and the vascular structures. Currently no data supports the routine use of dual modality PET CT or FDG PET in the local T staging of pancreatic adenocarcinoma. In N staging of disease, both FDG PET and CT perform poorly. Reported sensitivities and specificities for FDG PET are 46% and 63% respectively [87]. The low sensitivity of FDG PET to detect locoregional adenopathy is attributed to the close proximity of the peripancreatic lymph nodes to the primary tumor, which can lead to a partial volume averaging effect and thereby obscure tumor in the nodal structures [88]. In addition, FDG uptake in the peripancreatic lymph nodes is nonspecific; particularly, reactive adenopathy can be avid or "hot" on FDG PET and may be encountered after biopsy of the primary pancreatic neoplasm.

FDG PET has the ability to identify distant metastases. In a large series of patients with pancreatic malignancies, reported sensitivity and specificity of FDG PET for detecting hepatic metastases > 1cm was respectively 68% and 95%. Smaller lesions could be detected with the same specificity but lower sensitivity of 43% [89].

The most important cause of false positives in these studies was intrahepatic cholestasis. FDG PET may detect occult peritoneal metastases, but only with difficulty. In approximately 25% of cases, however, poorly localized and microscopic disease may not be confirmed.

The utility of PET still remains controversial as some authors suggest that does not provide any additional information whereas other investigators support that it is complementary to conventional imaging in detecting distant metastases [90]. In conclusion, FDG PET has not yet been shown to be a valid population wide screening tool or to have a clear role in routine imaging related to the management of pancreatic cancer, including diagnosis, staging or prognostication.

As FDG PET has poor anatomical definition and spatial resolution capabilities, CT and EUS may be best suited to local staging of pancreatic disease to determine if the patient is a surgical candidate. To achieve this modality's full potential, combined PET CT should be performed, with the CT component optimized with intravenous contrast to provide full diagnostic information. However, the best use of PET CT must be further investigated to clearly define the criteria where the addition of FDG PET to CT would be additive. The existing evidence suggests that FDG PET has limited utility in initial staging. The strength of functional imaging lies in its ability to detect pathology, irrespective of lesion morphology.

This innate property gives FDG PET its strength in detecting small as well as cystic lesions and in differentiating benign from malignant disease. Thus, FDG PET may sometimes change the management strategy by providing a more precise diagnosis.

Endoscopic Ultrasonography

Pancreatic cancers are usually visualized on EUS as more or less well demarcated echo poor lesions, which depending on their exact morphology and size are homogeneous or inhomogeneous, with echo rich spots or even cystic spaces (Figure 29, 30) [91]. Nevertheless, small pancreatic carcinomas can also be recognized as echo poor and well demarcated lesions, thus resembling pancreatic tumors of the endocrine type, or display a pattern of focal inhomogeneity. With more advanced tumor stages, pancreatic cancers become more inhomogeneous and start to infiltrate into neighboring organs and major vascular structures [92]. Various criteria have been initiated to demonstrate vascular involvement in pancreatic cancer including lack of the hyperechoic interface between the vessel wall and the tumor, tumor infiltration in the vascular lumen, lack of visualization of a major vessel in the presence of collateral ones, or other indirect signs such as proximity of the tumor mass to vessels, or even mass size [93]. The accuracy and usefulness of these criteria remains under debate. In most cases of pancreatic cancer, some suspicion has already been raised by other imaging modalities before EUS is performed to visualize and stage the disease.

As previously mentioned, patients presenting with clinical evidence of a pancreatic neoplasm are initially imaged with transabdominal U/S. If the suspicion is further confirmed, a CT and/or EUS are usually suggested. Which examination should be performed first remains a topic of dispute. Despite attempts to gather objective data to answer the question, constant advancements in imaging technology render this a difficult task. Thus, despite existing reports (which are evolving and ambiguous anyway), the decision of the imaging procedure of choice for the management of pancreatic tumors is mostly dependent on test availability, local expertise, and referral patterns in everyday practice. Therefore, due to the wide access to helical CT scanners, CT is usually proposed prior to EUS in most centers. Combining clinical and laboratory data, together with initial imaging procedures in many cases is enough to confirm the diagnosis; further diagnostic evaluation is then unnecessary.

Figure 29. Radial EUS depiction of a relatively well demarcated echo poor lesion with inhomogeneous, echo rich spots indicative of a ductal adenocarcinoma of the pancreas.

Figure 30. Linear EUS detection of a less demarcated echo poor pancreatic adenocarcinoma with cystic spaces within.

There are cases, however, in which diagnosis of a pancreatic neoplasm may be less clear cut, especially when the original nature of a pancreatic mass remains vague. The frequent situation of questionable pancreatic head enlargement on routine CT remains an important indication for EUS [94].

Multiple imaging tests including EUS, CT, MRI, and perhaps PET compete as to which examination or combination of diagnostic modalities is the most preferable in these settings. Several studies have supported superiority of EUS in comparison with other imaging techniques, especially when small tumors are concerned, beginning from the method's initial steps [95]. The ability of performing FNA during the diagnostic procedure has to be regarded as an additional advantage of EUS (Figure 31). Tumor detection with EUS has remained consistently high throughout the years, as long as we are dealing with focal masses outside of full blown chronic pancreatitis [96]. On the other hand, the pancreas is screened stepwise from several stations in duodenum and stomach and there is no systematic study that has actually evaluated the real ability of EUS to fully cover the pancreas. Image quality probably also plays a pivotal role in the detection of subtle pancreatic malignancy. Additionally, electronic EUS scanning also provides the expanded diagnostic possibilities of modern U/S technologies. Pancreatic EUS images acquired by tissue harmonic imaging were assessed as significantly clearer compared with those obtained by standard imaging. In the difficult issue of differential diagnosis between benign and malignant pancreatic mass lesions, good sensitivity and specificity values were reported for the clinical use of power Doppler and contrast enhanced EUS. However, it is apparent that these results need to withstand the test of time and be further assessed by well-documented surveys [97].

The major advantage of EUS for pancreatic cancer detection even in the era of recent imaging advances seems to be its high negative predictive value. Recent data support that absence of a circumscribed mass on EUS performed by an expert endosonographer can reliably exclude pancreatic cancer, especially when the pretest probability is low or indeterminate [98]. Comparisons of EUS with other imaging modalities show that, although it is not a 100% foolproof method, EUS still remains one of the best choices to detect a pancreatic neoplasm.

Figure 31. EUS FNA diagnostic procedure for pancreatic adenocarcinoma.

However, it should be emphasized that many of the studies comparing EUS and other cross sectional imaging techniques are characterized by the absence of blinding amongst examiners, and therefore, an objective evaluation of superiority of one test over another is inaccurate [99]. In everyday clinical practice, the role of CT, EUS, and the other imaging tests that might be available is rather complementary concerning the diagnosis and staging of pancreatic cancer.

EUS FNA is currently an established minimally invasive means of tissue acquisition, the implementation of which decisively broadened the spectrum of EUS by allowing direct transmural diagnosis (Figure 32). EUS FNA can therefore be extremely useful for various indications such as suspected pancreatic cancer, diagnosis of pancreatic carcinoma, or differential diagnosis of a pancreatic mass or smaller lesion [100]. Although criteria of EUS FNA remain rather controversial, the palliative setting where tissue confirmation is required prior to commencing chemotherapy or combined radiochemotherapy is a definitely undisputed indication of EUS FNA.

In contrast, in most cases of resectable tumors histological proof of pancreatic carcinoma it is not useful, since complete resection of the tumor is the only potentially curative approach [101]. The sensitivity, specificity, diagnostic accuracy, positive predictive value, and negative predictive value of EUS FNA, vary in published studies, but are generally high (e.g., 83%, 90%, 85%, 100% and 80% respectively in one multicenter study) [102]. Major complications after EUS FNA are rare. The rate of false positive diagnoses from EUS FNA is low in most papers.

Figure 32. EUS FNA procedure for histological confirmation of an advanced ductal adenocarcinoma with previous stenting of the common bile duct.

It has been reported that false positive diagnoses are attributed to interpretation errors. It is also evident that in most cases, only a positive diagnosis of malignancy counts.

It is obvious as with other puncture techniques that EUS guided FNP is mainly established to differentiate between benign and malignant conditions, or to allow parallel cytological and histological characterization of a lesion that is strongly suspected to be malignant, but in which different tissue diagnoses result in variable treatment approaches. In principle, clinical consequences must be clear and weighted against potential procedure associated risks before a EUS FNP is performed.

If a pancreatic mass is resectable and will also be operated on even if EUS guided FNP is negative, the procedure is not clinically implemented. EUS guided FNP is, however, also beneficial when other puncture methods have failed or when they are more invasive or risky. Pancreatic malignancy can be proved with a lower sensitivity, between 70% and 85%, and the influence on outcome is less clear.

In unresectable tumors, EUS FNA is obligatory when radiochemotherapy regimens are applied, and can be performed in one step with staging and perhaps celiac plexus blockade in case of severe pain [103]. In this occasion EUS is in competition with percutaneous puncture, but it seems that EUS FNA is preferable, not only because of its high diagnostic accuracy but also due to a possibly lower tumor seeding risk due to the shorter puncture canal.

Another interesting issue is to compare the value of EUS FNA with the other most available types of tissue sampling including CT guided and ERCP based. In order to address this question, recent prospective survey performed EUS FNA in 185 patients with known or suspected pancreatic masses.

Besides displaying the superiority of EUS in tumor detection (99% sensitivity to detect a mass for EUS vs. 57% for CT, $p < 0.0001$), EUS FNA proved superior compared with both CT and ERCP based tissue sampling, even in cases when the alternative acquisition methods were negative. Equally important, these results were achieved at a very low toll of complications [104]. Performance of EUS guided FNA of local lymph nodes in pancreatic cancer also makes sense only if a positive diagnosis would alter the management.

The role of EUS in locoregional staging of pancreatic cancer has been seen throughout the years both enthusiastically reaching levels of 93% for correct T staging and 88% for N staging, as well as more skeptically, even by groups which had previously published very optimistic results.

In a retrospective review of a cohort of 89 patients who were evaluated preoperatively with EUS for pancreatic adenocarcinoma, it was concluded that EUS was finally not as accurate as previously reported and not predictive for respectability [105]. This deterioration of results over time seems somewhat peculiar in view of the advances in EUS imaging.

However, it can partially be interpreted by carefully observing the populations examined in more recent studies. Patients with evidence of unresectable disease on high quality cross sectional imaging tests are increasingly not referred for EUS. This can be displayed when noticing the relative paucity of known T4, M1 lesions. Moreover, many patients with clearly resectable disease do not always undergo EUS.

In other words, the typical patients referred for EUS staging are cases with possibly marginal indications of curative surgery without clear cut evidence of irresectability [106].

Endoscopic Retrograde Cholangiopanceatography

ERCP indicates the presence of an irregular, nodular, rat-tailed eccentric ductal obstruction. Additional localized encasement with prestenotic dilatation may be depicted. Nevertheless, parallel obstruction of MPD and CBD at the same level referring to the "Double duct" sign remains the most common indication of the presence of a pancreatic tumor.

Angiography

Conventional angiography may be effective in detecting carcinomas of the body and tail of the pancreas indicating the presence of a hypovascular tumor with concomitant narrowing of major vascular structures as a result of displacement or occlusion by the malignant lesion.

Differential Diagnosis

- ✓ Islet cell carcinoma
- ✓ Chronic pancreatitis
- ✓ Metastases
- ✓ Lymphoma

10. PANCREATIC ISLET CELLS TUMORS

Definition

Neoplasms of the endocrine pancreas (neuroendocrine tumors-NETs) are relatively uncommon. Tumors arise from pancreatic endocrine cells including islet and Langerhans cells. Some NETs are functional, secreting peptide products that produce interesting clinical presentations.

NETs that are not associated with excess hormone levels and a recognizable clinical syndrome are considered nonfunctional. Multiple endocrine neoplasia (MEN) syndromes occur when related cells cause tumors in multiple sites.

Special immunohistochemical stains allow pathologists to confirm the peptide products being produced within the cells of a NET. However, the histologic characteristics of these neoplasms do not predict their clinical behavior, and malignancy is usually determined by the presence of local invasion and lymph node or hepatic metastases.

Unfortunately, most NETs are malignant, but the course of the disease is far more favorable than that encountered with pancreatic exocrine cancer.

The key to diagnosing these rare tumors is recognition of the classic clinical syndrome; confirmation is achieved by measuring serum levels of the elevated hormone. Localization of the tumor can be a challenging step, but once accomplished, the surgery is relatively straightforward [107, 108].

Surgical Interventions

- ✓ Complete surgical excision, often accomplished with insulinomas and in a minority of gastrinomas
- ✓ Complete surgical resection or embolization for nonfunctional NETs
- ✓ Debulking procedures to controlling symptoms
- ✓ Unresectable disease in the liver is often addressed with transarterial chemoembolization

Imaging Modalities

The role of imaging modalities in cases of pancreatic NETs is to establish the diagnosis and assess tumor resectability. Advanced imaging techniques are also recommended in localizing already diagnosed functioning pancreatic NETs for subsequent surgical removal.

In incidental lesions, imaging-guided FNA may be considered, depending on the possible influence on concomitant surgical management.

Computed Tomography

In Non-Enhanced CT (NECT) scanning functional tumors are depicted as lesions varying in size with cystic and necrotic areas. Additional calcifications may be obvious; whereas small tumors may not be identified. In Contrast-Enhanced CT (CECT) images relevant neoplasms are recognized as hyperdense lesions on the arterial phase due to their hypervascular appearance (Figure 33).

In case of functional insulinomas delayed scan presents a solid/ ring enhancement pattern. Enhancing metastases in the liver and lymph nodes are also detected in the same phase. Non-functional NETs are characterized with a similar depiction in NECT imaging.

Figure 33. Abdominal CT of a non-functioning pancreatic neuroendocrine tumor: Pancreatic phase of enhancement: a, b) Hypervascular inhomogeneous pancreatic head lesion with calcifications (thick black arrow).

Nevertheless, in CECT depiction an enhancing hypervascular viable tumor as well as metastatic lesions is identified along with non-enhancing cystic or necrotic areas. Liver metastases are often extensive even in relatively healthy patients due to early invasion of PV. The presence of calcifications is indicative of local invasion and highly malignant behavior [109, 110].

Magnetic Resonance Imaging

Functional tumors behave as hypointense lesions on fat-saturated T1WI images with insulinomas presenting a solid or ring-enhancement pattern (Figure 34). Nevertheless, on delayed enhanced similar sequences NETs could be depicted as hyperintense solid enhancing lesions. On T2WI sequences both primary and secondary lesions are recognized as hyperintense areas. On the contrary, small non-functional NETs are usually isointense on T1WI images while large tumors appear heterogeneous with cystic and necrotic areas. On T2WI images increased size NETs often appear hyperintense. Finally, fat-saturated delayed enhanced T1WI sequences may reveal a small otherwise undetectable hyperintense NET [111, 112].

Endoscopic Ultrasonography

Another consistent indication for EUS is the localization of NETs, although specific limitations were recently analysed. The clinical scenario here is mostly quite different, since in functional endocrine tumors, the diagnosis is established on the basis of laboratory tests, and imaging is performed to identify the tumor for subsequent surgical removal. Problems can arise, if EUS is the only method to define the presence of the tumor, other preoperative tests are negative, palpation during surgery is doubtful and intraoperative imaging is inconclusive. Preoperative marking of the tumors has recently been suggested as a helpful adjunct but has not been extended beyond case report status [113].

Figure 34. Abdominal MRI of an insulinoma: a) T2W image: Intermediate signal intensity lesion at the uncinate process of the pancreas (thick white arrow) b) 3D T1 Fat Suppression image: Arterial phase of enhancement: Homogeneously enhancing lesion at the uncinate process of the pancreas (thick white arrow).

The other setting are non-functional endocrine tumors which are mostly found incidentally even on transabdominal U/S [114]. They present as well demarcated, echo poor lesions in the pancreas (Figure 35, 36). FNA has been proposed to accomplish a tissue diagnosis, and further investigation from the specimens such as microsatellite loss analyses were recently performed and could be correlated to prognosis [115]. Therefore, EUS is still the diagnostic modality of choice in localizing NETs. In incidental lesions, FNA may be considered depending on the possible influence on subsequent management. Whether individual patients considered not being candidates for surgery can benefit from EUS-guided therapy using alcohol injection has to be evaluated [116].

Angiography

Conventional findings are indicative of hypervascular primary and secondary lesions. Subsequent hepatic venous sampling after intra-arterial stimulation of pancreas reveals elevated levels of hormones in case of functional NETs and decreased or absent elements for non-functional tumors.

Whole-Body Radionuclide Scanning

In contrast to pancreatic exocrine tumors, many of the NETs possess somatostatin receptors that allow them to be detected by a radiolabeled octreotide scan. A radioactive somatostatin analogue is injected intravenously, followed by whole-body radionuclide scanning.

Figure 35. EUS depiction of an islet cell tumor of the tail of the pancreas.

Figure 36. Power Doppler and contrast enhanced EUS findings indicative of advanced islet cell tumor of the pancreas and concomitant venous dilatation.

The success of this modality in localizing tumors and detecting metastases has decreased the use of older techniques such as angiography and selective venous sampling. Additional PET study with ^{68}Ga (DFO)-octreotide may be complimentary in cases with disseminated disease.

Differential Diagnosis

- ✓ Pancreatic ductal adenocarcinoma
- ✓ Mucinous cystic tumor of the pancreas
- ✓ Metastases
- ✓ Serous cystadenoma of the pancreas

11. SOLID AND PAPILLARY NEOPLASM

Definition

The term refers to a pancreatic mass of low malignant potential with solid and cystic features. Areas of central hemorrhage and necrosis are surrounded by solid and pseudopapillary structure [117].

Surgical Interventions

- ✓ Complete surgical excision

Imaging Modalities

The role of imaging modalities in case of solid and papillary neoplasm of the pancreas is to establish the diagnosis and assess whether surgical resection can be implemented.

Differential diagnosis of other cystic tumours categories and pseudocysts is only accomplished on the basis of specific imaging features as well as estimation of fluid aspirated with advanced imaging guided diagnostic procedures.

Ultrasound

Transabdominal U/S could only recognize fluid-debris levels with posterior enhancement.

Computed Tomography

NECT usually reveals an encapsulated, hypodense mass with limited calcification. Metastatic liver disease or lymph node involvement could rarely be encountered. In addition, on CECT images a well-defined heterogenous large mass is usually depicted.

Further low density areas of variable size within the lesion depend on the degree of concomitant hemorrhage and necrosis [118].

Magnetic Resonance Imaging

On T1WI images a large well-demarcated mass with central areas of mixed low and high signal intensity secondary to hemorrhage may be detected. The presence of capsule appears as rim of low intensity (Figure 37).

Angiography

Conventional angiography defines the presence of an avascular or hypovascular lesion depending on the degree of co-existing necrosis.

Figure 37. Abdominal MRI demonstrating a solitary pseudopapillary tumor of the pancreas: a) T2W image: Inhomogeneous predominantly high signal intensity lesion at the pancreatic tail (black asterisk), b) T1W image: Inhomogeneous predominantly low signal intensity, containing high intensity foci indicating hemorrhagic elements (black asterisk), c) Diffusion Weighted Image: Restricted diffusion pattern within the lesion (black asterisk), d) 3D T1 Fat Suppression image: Arterial phase of enhancement: Arterial enhancement of the solid portion of the lesion (thick red arrow).

Differential Diagnosis

- ✓ Pancreatic metastases
- ✓ Mucinous cystic tumor of the pancreas
- ✓ Exophytic gastric mass
- ✓ Serous cystadenoma of the pancreas
- ✓ Pseudocyst

12. PANCREATIC LYMPHOMA

Definition

Lymphoma can affect the pancreas. Primary involvement of the gland with no disease outside the pancreas also occurs. The clinical presentation often is similar to pancreatic adenocarcinoma, with vague abdominal pain and weight loss. Most common lymphoma is non-Hodgkin B cell subtype and is encountered usually in immunocompromised patients. Identification of a large mass often involving the head and body of the pancreas should raise suspicion. Percutaneous or EUS-guided biopsy will confirm the diagnosis in most cases.

If the diagnosis cannot be achieved preoperatively, laparoscopic exploration and biopsy are indicated [119].

Surgical Interventions

- ✓ There is no role for resection in the management of pancreatic lymphoma
- ✓ Endoscopic stenting to relieve jaundice followed by chemotherapy

Imaging Modalities

The role of imaging modalities in case of pancreatic lymphoma is to establish the diagnosis and achieve disease staging in order to avoid inadequate surgical interventions.

Differential diagnosis of other neoplastic disorders is only accomplished on the basis of specific imaging features as well as estimation of tissue aspirated with advanced imaging guided diagnostic procedures.

Computed Tomography

Pancreatic lymphoma is usually depicted as a homogeneous soft tissue mass with minimal enhancement. On occasion focal and circumscribed single or multiple masses may be encountered. Nevertheless, diffuse enlargement of pancreas with infiltrating tumor along with peri-pancreatic fat involvement could simulate acute pancreatitis (Figure 38).

Additional lymph node dissemination is often detected with lymphadenopathy below the level of renal veins consisting major determinant of the outcome. Dilatation of the pancreatic duct remains uncommon as well as encasement of the peri-pancreatic vessels [120, 121].

Figure 38. Abdominal CT in pancreatic lymphoma: Portal phase: a) Diffuse enlargement of the pancreatic tail in a patient with known Non Hodgkin lymphoma (black asterisk) b) Biopsy that revealed pancreatic involvement in lymphoma.

Differential Diagnosis

- ✓ Pancreatic ductal carcinoma
- ✓ Mucinous cystic tumor of the pancreas
- ✓ Pancreatic islet cell tumors

13. PANCREATIC METASTASES

Definition

The incidence of pancreatic metastases varies based on the primary malignant lesion. Solitary or multiple polypoid masses are usually recognized derived mainly from renal cell carcinoma (30%) and bronchogenic carcinoma (23%).

Cases of pancreatic secondary tumors due to advanced breast cancer, soft tissue sarcoma and primary tumors of the gastrointestinal track have also been described.

With regard to renal cell carcinoma it is common knowledge that may be isolated only to pancreas and detected occasionally several years or decades after initial diagnosis [122].

Surgical Interventions

- ✓ Surgical resection if metastasis is only isolated to the pancreas

Imaging Modalities

The role of imaging modalities in case of pancreatic metastases is to establish the diagnosis and achieve disease staging in order to avoid inadequate surgical interventions. Differential diagnosis of other neoplastic disorders is only accomplished on the basis of specific imaging features as well as estimation of tissue aspirated with advanced imaging guided diagnostic procedures.

Computed Tomography

Most common pancreatic metastases can be depicted as a discrete mass with variable enhancement pattern that usually mimics primary tumor.

Concomitant intra-abdominal metastases to the liver (36%), lymph nodes (30%) and adrenal glands (30%) may be recognized along with dilatation of the pancreatic duct or biliary tree and potential encasement of the major peri-pancreatic vascular structures [123].

Figure 39. Abdominal MRI demonstrating metastasis to the pancreas from lung cancer. a) Diffusion Weighted image: Small hyperintense lesion (restricted diffusion pattern) at the pancreatic head (thick red arrow) b) T1 Fat Suppressed image: Hypointense lesion at the pancreatic head (thick red arrow) c) 3D T1 Fat Suppressed image after contrast medium administration: Hypovascular lesion at the pancreatic head (thick red arrow).

Magnetic Resonance Imaging

On T1WI images hypointense lesions with variable fat saturation are usually revealed. Smaller tumors present homogenous enhancement. On T2WI sequences slightly heterogenous and moderately hyperintense lesions as well as diffuse, enlarged metastases described as hypo-intense nodules may be recognized (Figure 39).

Differential Diagnosis

- ✓ Pancreatic ductal carcinoma
- ✓ Mucinous cystic tumor of the pancreas
- ✓ Pancreatic islet cell tumors

Chapter 89

THE ROLE OF IMAGING IN ESOPHAGEAL SURGERY

***Efstathios Kotidis*, Konstantinos Sapalidis
and Manos-Georgios Pramateftakis***

Department of Surgery, Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT

The esophagus is a muscular tube connecting the pharynx with the stomach and represents an integral part of the digestive system. There is a wide range of diseases (congenital, functional, structural, trauma and neoplasia) affecting the esophagus. These combined with the fact that it is located in both the thoracic and the abdominal cavity, make the diagnosis and management of esophageal problems a significant challenge, even for the more experienced practitioners. Knowledge of the most current imaging technology can play a critical role in forming a successful strategy.

INTRODUCTION

The esophagus is a muscular tube connecting the pharynx with the stomach. It is 23-37 cm long with a diameter of 1-2 cm and is divided into three parts:

- a) cervical: the cervical esophagus is in continuity with the oropharynx, commences at the lower border of cricoid cartilage (at level of C5/6) or cricopharyngeus muscle and continuous until the level of the thoracic aperture.
- b) thoracic: extents from the thoracic aperture (T1) to the oesophageal hiatus (T11)
- c) abdominal: from oesophageal hiatus and is continuous with the cardia of the stomach at the gastro-oesophageal junction.

It courses inferiorly to the left of the midline in the neck and superior mediastinum returning to the midline at T5 before coursing to the left again of the midline in the posterior

* Corresponding Author's Email: skotidis@gmail.com.

mediastinum and in its inferior aspect curving anteriorly to pass through the diaphragm into the abdominal cavity. The esophagus has three normal constrictions, due to its compression against the adjacent structures that should not be confused for pathological constrictions: The *cervical constriction* due to the cricoid cartilage at the level of C5/6, the *thoracic constriction* due to the aortic arch at the level of T4/5 and the abdominal constriction at the oesophageal hiatus (T10/11).

Its arterial blood supply comes from the thyroid artery (upper third), esophageal branches of the thoracic aorta (middle third) and esophageal branches of the left gastric artery (lower third). Regarding the venous drainage, the upper third drains to the brachiocephalic veins, the middle to the azygos and the lower third to the left gastric vein. The lymphatic drainage follows the arterial supply. The nerve supply is from the sympathetic trunk and the vagal plexus. Histologically, the oesophagus is characterised by the lack of serosal layer. It consists of the outer muscularis propria, the inner muscularis propria, the submucosa, the muscularis mucosae and the mucosa. It is covered by stratified squamous epithelium that abruptly changes to columnar epithelium in the lower oesophagus [1, 2]. The commonest pathologies of the esophagus include oesophageal cancer, benign oesophageal neoplasms, hiatus hernias, achalasia and other motility disorders, gastroesophageal reflux disease (GORD), esophageal rupture (Boerhaave syndrome), esophageal strictures (Schatzki ring or oesophageal web) and esophageal diverticula [2]. The radiographic imaging modalities of the esophagus include barium swallow, CT, endoscopic ultrasonography, MRI, and PET/CT. Barium swallow is the main radiological method of assessing the oesophagus. Endoscopic ultrasonography is used for evaluation of the depth of the oesophageal cancer. CT or MRI are used to diagnose hiatal hernias, diverticuli and tumors of the esophagus and to stage esophageal cancer. PET/CT is only use in staging esophageal malignancies [2].

CONGENITAL DISORDERS

Oesophageal atresia is the commonest of the congenital anomalies of the esophagus. It refers to an absence in contiguity of the oesophagus due to an inappropriate division of the primitive foregut into the trachea and oesophagus. It may be suspected on antenatal ultrasound or in the neonate due to inability to swallow saliva or milk, aspiration during early feedings, or failure to successfully pass a catheter into the stomach.

It is frequently associated with a tracheo-oesophageal fistula. As such, the types of oesophageal atresia / tracheo-oesophageal fistula can be divided into proximal atresia with distal fistula (85%) isolated oesophageal atresia (8-9%), isolated fistula (H-type) (4-6%), double fistula with intervening atresia (1-2%), proximal fistula with distal atresia [3, 4] (1%).

Radiographic Features

A plain chest x ray may show a dilated pharyngeal pouch, or the presence of air in the stomach and bowel in the setting of oesophageal with a distal tracheo-oesophageal fistula.

If an oesophago-gastric (feeding) tube insertion has been attempted this may show the tube blind looping and turning back at the upper thoracic part of the oesophagus or heading into the trachea and/or bronchial tree.

A contrast swallow fluoroscopy may show contrast blindly ending and pooling in an oesophageal stump and/or may show evidence of the tracheo-oesophageal fistula (Images 1, 2). CT scan with 3D detailed visualisation of anatomy has also been trialed but is not part of routine investigation.

Image 2. The same patient after the administration of water soluble contrast.

FOREIGN BODIES

The presence of foreign bodies in the esophagus is more common in children. They are usually impacted in the first natural stricture of the esophagus at the level of the cricopharyngeal muscle. In most cases the history along with a plain x ray are enough for the diagnosis [5, 6, 7] (Images 3, 4).

ESOPHAGEAL DIVERTICULA

Esophageal diverticulum is a pouch arising from the esophagus. Its lumen is in continuity with the esophageal lumen. They can occur in all ages but are more frequent in adults and elderly people. Based on their pathology, they are divided into *true* and *false* diverticula. True diverticula include all esophageal layers while false diverticula contain only mucosa and submucosa herniating through the muscular layer (e.g., Zenker's diverticulum).

Based on their pathophysiology they are divided into *traction diverticula* which occur secondary to pulling forces on the outer aspect of the oesophagus and *pulsion diverticula* which occur secondary to increased intraluminal pressure (e.g., Zenker diverticulum).

According to their location, they are divided into upper, middle and lower diverticula. Upper diverticula are generally pulsion diverticula and include Zenker's and Killian Jamieson diverticulum. Zenker's diverticulum is actually a pharyngeal pouch, located just proximal to the upper esophageal sphincter. Killian Jamieson diverticulum is infrequently encountered compared with the Zenker's and is located just below the cricopharyngeal muscle.

The middle esophageal diverticula can be both traction and pulsion diverticula (Image 5). Traction diverticula may occur secondary to scarring, fibrosis and inflammatory processes in the mediastinum pulling on the oesophageal wall.

They are more frequently located close to the tracheal bifurcation. They are usually small, rarely exceeding 2cm in diameter and in most cases asymptomatic.

Pulsion diverticula are usually false diverticula and occur secondary to abnormally increased intraluminal pressure against a weak esophageal segment.

Image 3. Impacted foreign body (coin). Anteroposterior view.

Image 4. Impacted foreign body (coin). Lateral view.

Image 5. Zenker's diverticulum.

Finally, lower or epiphrenic oesophageal diverticula are pulsion diverticula that occur through weak or defective sites of the muscular layer of the lower esophagus, usually in combination with achalasia or hiatus hernias. They are usually larger than middle esophageal diverticula and may be complicated with infection or perforation.

A rare condition mimicking diverticula is esophageal pseudodiverticulosis. It may occur in all age groups, but more commonly in the 6th and 7th decades. They represent dilated excretory ducts of the deep oesophageal mucosal glands [8, 9].

Radiographic Features

A barium swallow is the study of choice. *Zenker's diverticula* present as an outpouching arising from the midline of the posterior wall of the distal pharynx near the pharyngoesophageal junction. The pouch is best identified during swallowing and is best seen on the lateral view, on which the diverticulum is typically noted at the C5-6 level (Image 6). *Epiphrenic diverticula* present as outpouching of the distal esophagus, best seen in prone oblique views (Image 7).

Pseudodiverticula are best seen with a single contrast, rather than a double contrast, thin barium examination (Image 8). The findings are numerous tiny flask-shaped outpouchings usually diffusely distributed or clustered. CT scan may also be used to confirm the diagnosis and to provide more anatomic information that may facilitate the surgical treatment [9].

ESOPHAGEAL VARICES

Esophageal varices are extremely dilated submucosal veins of the lower third of the esophagus. They are most often a consequence of portal hypertension, commonly due to cirrhosis; patients with esophageal varices have a strong tendency to develop bleeding.

The majority of blood from the esophagus is drained via the esophageal veins to the azygos vein, which in turn drains directly into the superior vena cava. These veins have no part in the development of esophageal varices. The remaining blood from the esophagus is drained into the superficial veins lining the esophageal mucosa, which drain into the left gastric vein (coronary vein), which in turn drains directly into the portal vein. These superficial veins (normally only approximately 1 mm in diameter) become distended up to 1-2 cm in diameter in case of portal hypertension. Normal portal pressure is approximately 9 mmHg compared to an inferior vena cava pressure of 2-6 mmHg.

This creates a normal pressure gradient of 3-7 mmHg. If the portal pressure rises above 12 mmHg, this gradient rises to 7-10 mmHg. A gradient greater than 5 mmHg is considered portal hypertension. At gradients greater than 10 mmHg, blood flow through the hepatic portal system is redirected from the liver into areas with lower venous pressures. This means that collateral circulation develops in the lower esophagus, abdominal wall, stomach, and rectum. The small blood vessels in these areas become distended, becoming more thin-walled, and appear as varicosities [10].

Radiographic Features

Lobulated masses in the posterior mediastinum or silhouetting of the aorta may be seen in plain x rays. Barium swallow with small amount of barium is the study of choice. Relaxation of the esophagus, in order not to compress the varices, is important.

Therefore, a sustained valsalva manoeuvre is important to preclude swallowing, since each swallow initiates a primary peristaltic wave that lasts for at least 10-30 seconds. The usual findings are thickened and interrupted mucosal folds, tortuous radiolucencies of variable size and location or “worm eaten” smooth lobulated filling defects (Images 9, 10).

A CT scan may also be useful to confirm the diagnosis. The commonest appearance is thickened esophageal wall with lobulated outer contour, scalloped esophageal luminal masses and marked enhancement following dynamic CT. In case of paraesophageal varices right or left sided soft tissue masses may be seen [10, 11, 12] (Image 11).

ESOPHAGEAL STRICTURES

Oesophageal strictures refer to any persistent intrinsic narrowing of the oesophagus.

They are usually caused by inflammatory or neoplastic processes such as caustic ingestion, mediastinal radiation, esophagitis, scleroderma or congenital stenosis.

Radiographic Features

Benign strictures typically show smooth concentric narrowing. Malignant strictures are characteristically abrupt, asymmetric, eccentric narrowings with irregular, nodular mucosa (Image 12).

Image 9. Esophageal varices on barium swallow test.

Image 10. Gastric varices.

Tapered margins may occur with malignant lesions because of the ease of submucosal spread of tumour. All esophageal strictures should be investigated with upper endoscopy to rule out malignancy [13, 14].

ESOPHAGEAL PERFORATION

Esophageal perforation is a rare but serious medical emergency with very high mortality rate, especially if the diagnosis is delayed.

Most perforations are iatrogenic, post dilatation or thoracic surgery. Other causes include trauma, foreign body ingestion, erosive material ingestion, esophageal cancer or spontaneous post vomiting rupture (Boerhaave syndrome). If perforation is not detected during the instrumentation, the patient will develop neck, chest or epigastric pain, dyspnoea, dysphagea and sepsis [15]. Subcutaneous emphysema may also be present.

Image 11. CT scan demonstrating esophageal varices.

Image 12. Benign esophageal stricture secondary to esophagitis. A large sliding hiatus hernia is also seen.

Radiographic Features

Plain chest x-ray may show pneumomediastinum, pneumothorax and/or pleural effusion indicative of mediastinitis. Contrast swallow with water soluble agent is more sensitive, and should be done within 24 hours to confirm the diagnosis. CT scan may also be useful to evaluate the extent of pleural effusion and mediastinitis.

Once diagnosed, the esophageal perforation should immediately be treated either endoscopically or laparoscopically [15, 16].

Image 13. Gastrographin swallow demonstrating iatrogenic perforation of the esophagus.

Image 14. CT scan after iatrogenic perforation of the esophagus. The scan shows collection of fluid and air in the mediastinum.

SCHATZKI RING

Schatzki ring is a relatively common lower esophageal ring found in nearly 10% of barium swallows. It is located 2-3 cm above the hiatus and is thought to be a congenital anomaly formed by redundant pleats of mucosa. Its clinical presentation depends on its luminal diameter.

Most rings are asymptomatic unless the luminal diameter is < 13mm. In such cases they present with dysphagia especially to solid food. Interestingly, patients with Schatzki ring have lower incidence of Barrett's esophagus. If they are symptomatic, boogie or balloon dilatation is the treatment of choice [17].

Radiographic Features

Single contrast barium swallow is the study of choice. Its sensitivity is even higher than endoscopy. A Valsalva manoeuvre may be useful to increase the sensitivity of the test.

A circumferential narrowing at the gastro-oesophageal junction, often a few centimeters above the diaphragmatic hiatus, is the commonest feature (15).

HIATUS HERNIA

Hiatus hernia (HH) is the herniation of abdominal viscera through the esophageal hiatus into the posterior mediastinum or the thoracic cavity. Depending on the location of the gastroesophageal junction, hiatus hernias are divided into sliding, where the junction is displaced up in the posterior mediastinum and paraesophageal hernias, where the junction is not displaced. Many patients with HH are asymptomatic and it is an incidental finding. However, symptoms may include epigastric or chest pain, post prandial fullness, nausea and

vomiting. Sometimes HH are considered synonymous with gastro-oesophageal reflux disease (GORD) but there is a poor correlation between the two conditions. The most common content of a HH is the stomach. Large HH containing stomach may result in gastric volvulus, which in turn presents as intestinal obstruction and may result in ischaemia or infarction [18].

There are two main types of hiatus hernia, although they may co-exist:

Sliding Hiatus Hernia

This is the most common type of hiatus hernia (95%). The gastro-oesophageal junction (GOJ) is usually displaced by more than 2 cm above the hiatus. The oesophageal hiatus is often abnormally widened to 3-4 cm (the upper limit of normal is 15 mm).

The gastric fundus may also be displaced above the diaphragm and present as aretrocardiac mass on a chest radiograph. The presence of an air-fluid level in the mass suggests the diagnosis. Small, sliding hiatus hernias commonly reduce in the upright position.

Image 15. Schatzki ring.

The mere presence of a sliding hiatus hernia is of limited clinical significance in most cases. The function of the lower oesophageal sphincter and the presence of gastro-oesophageal reflux disease (GERD) are the crucial factors in producing symptoms and causing complications [18, 19].

Para-Oesophageal Hiatus Hernia

The para-oesophageal hiatus hernia is much less common than the sliding type (5%). The GOJ remains in its normal location while a portion of the stomach herniates above the diaphragm.

Mixed Hiatus Hernia

The two types of hiatus hernias may also coexist. The GOJ is displaced into the thorax with a large portion of the stomach, which is usually abnormally rotated.

Radiographic Features

A plain x ray may reveal retrocardiac opacity with air – fluid level. Single contrast barium swallow is diagnostic on most cases (Image 16, 17).

CT scan may be necessary to clarify in more detail the content and the relations of the hernia sack, especially in large paraesophageal hernias (Image 18). The differential diagnosis includes retrocardiac lung abscess or empyema and epiphrenic esophageal diverticulum [18].

Image 16. Sliding hiatus hernia.

Image 17. Paraesophageal hiatus hernia.

Image 18. CT scan demonstrating sliding hiatus hernia.

GASTROESOPHAGEAL REFLUX DISEASE (GERD)

Gastroesophageal reflux disease occurs when the amount of gastric juice that refluxes into the esophagus exceeds the normal limit, causing symptoms with or without associated esophageal mucosal injury. Typical esophageal symptoms include heartburn, regurgitation and dysphagia.

Abnormal reflux can also cause atypical (extraesophageal) symptoms, such as coughing and/or wheezing, hoarseness, sore throat, otitis media, noncardiac chest pain, enamel erosion or other dental manifestations. A history of nausea, vomiting, or regurgitation should alert the physician to evaluate for delayed gastric emptying. Patients with suspected gastroesophageal reflux disease should be investigated with upper gastrointestinal endoscopy, esophageal manometry and ambulatory 24-hour pH monitoring. Ambulatory 24-hour pH monitoring is the criterion standard in establishing a diagnosis of gastroesophageal reflux disease [19].

Radiographic Features

Upper gastrointestinal contrast-enhanced studies are the initial radiologic procedure of choice in the workup gastroesophageal reflux disease. Plain chest radiographic findings are not useful in evaluating of this condition, but they are helpful in assessing pulmonary status and basic anatomy. Chest images may also demonstrate a large hiatal hernia, but small hernias can be easily missed. Currently, no role exists for computed tomography scanning, magnetic resonance imaging, or ultrasonography in the routine evaluation of patients with reflux disease [20].

Achalasia

Achalasia is a primary esophageal motility disorder characterized by the absence of esophageal peristalsis and impaired relaxation of the lower esophageal sphincter (LES) in response to swallowing. The LES is hypertensive in about 50% of patients. These abnormalities cause a functional obstruction at the gastroesophageal junction (GEJ).

It is most frequently seen in middle and late adulthood (30-70 years of age) with no gender predilection. In most cases achalasia is idiopathic, however an identical appearance is seen in patients with Chagas disease.

Authors differ as to whether they reserve the term achalasia for idiopathic cases, or whether they include Chagas disease. Symptoms of achalasia include dysphagia (most common), regurgitation, chest pain, heartburn and weight loss. Initially symptoms are intermittent. Patients may also present with a complication of long standing achalasia:

- oesophageal carcinoma: is the most dreaded complication and is seen in approximately 5%, and most often in the mid oesophagus. It is thought to relate to the chronic irritation of the mucosa by stasis of food and secretions.
- aspiration pneumonia and eventually abscess formation
- candida oesophagitis
- acute airway obstruction: this is a rare complication requiring immediate esophageal decompression with nasogastric tube

Esophageal manometry is the criterion standard in the diagnosis of achalasia. Findings include incomplete LES relaxation in response to swallowing, high resting LES pressure, absent esophageal peristalsis.

Ambulatory esophageal pH monitoring to rule out gastroesophageal reflux disease and determine if abnormal reflux is being caused by treatment may also be necessary. Esophagogastroduodenoscopy to rule out cancer of the GEJ or fundus is usually done in most cases. Concomitant endoscopic ultrasonography is necessary if a tumor is suspected [21].

Radiographic Features

Chest x-ray findings include:

- right convex opacity behind right cardiac border; occasionally left convex opacity if thoracic aorta tortuous
- air-fluid level due to stasis in thoracic esophagus filled with retained secretions and food
- small or absent gastric air bubble
- anterior displacement and bowing of trachea on the lateral view

The chronic presence of fluid debris in the esophagus makes patients very prone to aspiration and thus patchy bilateral alveolar opacities representing acute or chronic aspiration pneumonia may be seen.

Barium Swallow

A barium swallow is able to not only confirm that the esophagus is dilated but is also able to assess for mucosal abnormalities (Image 19).

Image 19. Achalasia of the esophagus.

Findings include:

- failure of normal peristalsis to clear the esophagus of barium when the patient is in the recumbent position, with no primary waves identified
- uncoordinated, non-propulsive, tertiary contractions
- esophageal body dilatation, which is typically maximal in the distal esophagus
- pooling or stasis of barium in the esophagus when the esophagus has become atonic or non contractile (late feature in the disease)
- when barium column is high enough (patient standing) the hydrostatic pressure can overcome the LOS pressure allowing passage of esophageal content
- incomplete LOS relaxation that is not coordinated with esophageal contraction
- bird beak sign

CT

Patients with uncomplicated achalasia demonstrate a dilated thin walled esophagus filled with fluid/food debris. Overall CT has little role in directly assessing patients with achalasia, but is useful in assessing common complications. Careful assessment of the wall of the esophagus should be undertaken to identify any focal regions of thickening which may indicate malignancy. The lungs should be inspected for evidence of aspiration.

Differential Diagnosis

A number of entities may mimic achalasia, forming the so called 'achalasia pattern.' They include central and peripheral neuropathy, scleroderma, oesophageal malignancy or gastric carcinoma commonly referred as pseudoachalasia, oesophageal stricture, Chagas disease, non-specific oesophageal motility disorder and diffuse oesophageal spasm.

Treatment

The American College of Gastroenterology released new guidelines for the diagnosis and management of achalasia in July 2013. Treatment recommendations are as follows:

- Initial therapy should be either graded pneumatic dilation (PD) or laparoscopic surgical myotomy with a partial fundoplication in patients fit to undergo surgery
- Procedures should be performed in high-volume centers of excellence
- Initial therapy choice should be based on patient age, sex, preference, and local institutional expertise
- Botulinum toxin therapy is recommended for patients not suited to PD or surgery
- Pharmacologic therapy can be used for patients not undergoing PD or myotomy and who have failed botulinum toxin therapy (nitrates and calcium channel blockers most common) [20].

ESOPHAGEAL CYSTS

Esophageal cysts were initially described esophageal cysts as duplications. They can be divided into two categories. Simple epithelial-lined cysts and esophageal duplication, which is an embryologic duplication of a portion of the muscle and submucosa of the esophagus without epithelial duplication. Esophageal cysts are rare. Many patients with esophageal cysts are asymptomatic and never diagnosed. The true incidence of esophageal cysts is unknown, since no large study has defined it.

They are usually grouped with other benign lesions of the esophagus, comprising up to 20% of benign esophageal lesions. Up to 80% of them are diagnosed in childhood.

The diagnosis and treatment of esophageal cysts is still evolving. Diagnosis is aided by the relatively recent developments of CT scans and endoscopic ultrasonography. Treatment is currently moving from thoracotomy to less-invasive procedures, including video-assisted thoracoscopic surgery (VATS) and endoscopic treatment.

Symptoms are caused by compression of surrounding structures. Sixty percent of esophageal cysts occur in the lower third of the esophagus, where difficulty swallowing from compression is the most common symptom; 20% occur in the upper third of the esophagus, where respiratory difficulty from compression of the tracheobronchial tree is the most common symptom; and 20% occur in the middle third of the esophagus, where retrosternal chest pain and difficulty swallowing are the most common symptoms. Posterior cysts in the lower third of the esophagus can cause cardiac arrhythmias. The larger the cyst, the greater the chance of it causing symptoms [22].

Maldevelopment of the posterior division of the primitive foregut is the embryologic defect responsible for esophageal cysts. Esophageal cysts develop from aberrant elements of

the esophageal wall. Simple cysts are duplication of the epithelium, whereas true esophageal duplications are duplications of the submucosa and the muscle wall without duplication of the epithelium. The lining of the cyst can vary and can include squamous columnar, cuboidal, pseudostratified, ciliated, and gastric mucosae. Hemorrhage can be the presenting symptom if gastric mucosa is present in the cyst. The other types of mucosa are not specifically associated with particular symptoms [22].

Radiographic Features

Plain chest radiographs can reveal a cyst within the mediastinum.

Barium swallow studies reveal compression of the esophagus without ulceration.

Image 20. CT scan. Achalasia of the esophagus.

CT scan reveals a fluid-filled cystic structure originating from the esophagus (Image 21).

Endoscopic ultrasonography reveals a cystic, filled structure in connection with the esophagus.

MRI scans can also help diagnose esophageal cysts.

All cysts should be resected unless the patient's other medical ailments prohibit operation.

BENIGN ESOPHAGEAL NEOPLASMS – LEIOMYOMA

Benign neoplasms of the esophagus are extremely rare that constitute less than 1% of esophageal neoplasms. A number of benign esophageal tumors have been recognized. They include leiomyoma, fibrovascular polyp of the esophagus, papilloma, fibroma, haemangioma, hamartoma and neurofibroma. Esophageal leiomyoma is the most common, representing nearly two thirds of benign esophageal tumors.

Leiomyomas represent a hyperproliferation of bundles of smooth muscle cells that are well-demarcated by adjacent tissue or by a smooth connective tissue capsule. They usually arise as intramural growths, most commonly along the distal two thirds of the esophagus. They are multiple in approximately 5% of patients. The majority is discovered incidentally or during investigation for dysphagia. The clinical presentation would often depend on the size

of tumour. Small tumours (< 5 cm) usually have no symptoms, while large tumours may cause dysphagia, regurgitation, oesophageal obstruction, chest pain, cough or bleeding. They typically involve the mid to distal oesophagus [23, 24].

Radiographic Features

Esophageal leiomyoma can be visualized using barium swallow. The classic appearance is a smooth concave mass underlying intact mucosa.

Distinct sharp angles are seen at the junction of the tumor and normal tissue. Encroachment onto the esophageal lumen usually is observed (Image 22).

Esophageal ultrasonography can be helpful in demonstrating a smooth, typically round, mass located in the muscularis without encroachment into the overlying mucosa or underlying adventitia.

Image 21. Esophageal duplication cyst.

CT scan is even more accurate in diagnosing leiomyomas of the esophagus. Common findings include ovoid intramural solitary mass with a smooth surface, narrowing of oesophageal lumen, displacement of the esophagus, moderate diffuse contrast enhancement with no signs of invasion of adjacent tissues.

The presence of calcifications is almost pathognomonic. Imaging differential considerations include oesophageal carcinoma, leiomyosarcoma of the oesophagus, oesophageal hamartoma and other mediastinal tumours arising close to the oesophagus. The overall prognosis is excellent. If tumour is small (< 5 cm) and asymptomatic treatment is non necessary. Otherwise surgical enucleation is recommended [23].

ESOPHAGEAL CARCINOMA

Carcinoma of the esophagus remains a devastating disease because it is usually not detected until it has progressed to an advanced incurable stage. Oesophageal cancer is responsible for < 1% of all cancers and 4-10% of all gastrointestinal malignancies.

It represents a disease in epidemiologic transition. Until the 1970s, the most common type of esophageal cancer in the United States was squamous cell carcinoma, which has

smoking and alcohol consumption as risk factors; since then, there has been a progressive increase in the incidence of esophageal adenocarcinoma, for which the most common predisposing factor is gastroesophageal reflux disease (GERD) [25].

Presenting signs and symptoms of esophageal cancer include dysphagia, initially for solids and eventually progressing to include liquids, weight loss, bleeding epigastric or retrosternal pain, bone pain with metastatic disease, hoarseness, persistent cough. Clinical examination is typically normal unless the cancer has metastasized. In metastatic disease the commonest findings are hepatomegaly and lymphadenopathy in the laterocervical or supraclavicular areas. Diagnosis is based on esophagogastroduodenoscopy which allows direct visualisation and biopsy of the tumor [25, 26].

Image 22. Esophageal leiomyoma.

Radiographic Features

Barium esophagography is a useful initial examination in the evaluation of a patient with esophageal complaints. It is unique among esophageal studies for assessing both morphology and motility and therefore remains the study of choice for characterization of esophageal strictures. Esophageal carcinoma may demonstrate a variety of appearances on barium esophagram such as irregular stricture, pre-stricture dilatation with 'hold up' and shouldering of the stricture (Image 24, 25, 26).

Image 23. CT scan. Esophageal leiomyoma.

Image 24. Barium swallow illustrating carcinoma of the lower third of the esophagus in a patient with sliding hiatus hernia.

Image 25. Barium swallow illustrating esophageal carcinoma.

Image 26. Barium swallow illustrating carcinoma of the middle third of the esophagus.

Esophageal endoscopy permits direct inspection and biopsy of the esophageal mucosa for histologic diagnosis. For the purpose of staging esophageal carcinoma, EUS (Image 27), contrast-enhanced CT (Images 28, 29), and PET (Image 30) each offer unique information [26].

Image 27. EUS showing adenocarcinoma of the esophagus.

Image 28. CT scan in a patient with adenocarcinoma of the gastroesophageal junction.

Each of the diagnostic modalities has its limitations. Barium esophagography has optimal sensitivity for the detection of lesions when a double-contrast technique is used. Such technique requires that the patient be able to stand upright, which may not be possible with all patients. For bulkier obstructive lesions, an air-contrast technique may not be possible, and a detailed mucosal examination may not be achieved distal to the obstruction.

A notable limitation of CT in diagnosis involves the characterization of lymph nodes. With CT scans, size criteria are used to determine possible metastatic involvement; however, lymph nodes may be enlarged because of infectious or inflammatory aetiologies. Conversely, subcentimeter lymph nodes may harbour metastatic tumor.

Endoscopic ultrasonography (EUS) is highly operator dependent. Another limitation of EUS is its inability to pass the malignant stricture with the transducer. This limitation may result in an incomplete examination.

However, the use of a dedicated 8-mm-diameter esophagoprobe for EUS allows complete examination in most patients [25-27].

With PET, the resolution and cost remain the primary limitations. Subcentimeter foci of tumor metabolism may not be detected.

Staging of Esophageal Carcinoma

Contrast-enhanced CT plays an important role in the staging of esophageal carcinoma. Attention is directed to determining the extent of the local tumor, invasion of mediastinal structures, involvement of supraclavicular mediastinal or upper abdominal lymph nodes and distant metastases. These observations are useful in distinguishing between T3 and T4 lesions and in determining the N and M status.

CT examination should extend from the thoracic inlet through the liver. Routine oral contrast material should be administered. It should be obtained during full inspiration when patients are evaluated for esophageal carcinoma since inward bowing of the trachea and mainstem bronchi during expiration may produce the false impression of tracheobronchial invasion. Common CT findings include eccentric or circumferential wall thickening > 5 mm,

perioesophageal soft tissue and fat stranding, dilated fluid- and debris-filled oesophageal lumen proximal to an obstructing lesion.

Tracheobronchial invasion appears as displacement of the airway (usually the trachea or left mainstem bronchus) as a result of mass effect by the oesophageal tumour. A careful search for lymph nodes is an essential component of the interpretation.

Image 29. CT scan illustrating squamous cell carcinoma of the middle esophagus.

Image 30. PET scan and PET/CT in a patient with adenocarcinoma of the lower third of the esophagus.

A short-axis diameter exceeding 1 cm is considered abnormal for lymph nodes in all mediastinal locations except those in the subcarinal region, in which 1.4 cm is the upper limit of normal. Because lymph nodes may harbor metastases without being enlarged, noting the location of any identified lymph nodes is important. In addition, remembering that lymph nodes may be enlarged because of inflammatory or infectious aetiologies is important. Its sensitivity for the detection of lymph node metastases is in the range of 60-80%. Its specificity is higher, approximately 90%.

Magnetic resonance imaging (MRI) has the advantage of direct multiplanar imaging capabilities, which may be of particular use in assessing tracheobronchial, aortic, and pericardial invasion. Currently, MRI has not yielded other significant advantages compared

with CT in the staging of esophageal carcinoma. The sensitivity and specificity of MRI for the determination of tumor invasion are equivalent to those of CT.

EUS, unlike CT, allows visualization of the distinct layers within the esophageal wall. Alternating circumferential layers define the mucosal interface (hyperechoic), the mucosa (hypoechoic), the submucosa (hyperechoic), the muscularis propria (hypoechoic), and the adventitial interface (hyperechoic). Such resolution permits the distinction of T1, T2, T3, and T4 tumors. Esophageal carcinoma appears as a hypoechoic lesion disrupting the normal circumferential layers.

However, with standard EUS equipment, often only 3 layers are seen in the esophageal wall: the mucosa and submucosa (hyperechoic), the muscularis propria (hypoechoic), and the adventitial interface (hyperechoic). Local lymph nodes are also demonstrated by using EUS. Nodes are considered malignant if they are round, if they are hypoechoic, and if they have well-defined borders. Usually, benign nodes are hyperechoic and less well defined [27, 28].

T-stage accuracy with EUS is in the range of 79-94%. At this time, only EUS is useful in distinguishing T1 and T2 lesions. N-stage accuracy is in the range of 69-90%. Distant metastases cannot be reliably identified with EUS because of the limited field of view.

PET is quickly becoming a standard oncologic imaging modality. The technique is useful not only for the primary detection of tumor and metastases, but also for the further characterization of abnormalities discovered by using other imaging modalities.

The sensitivity of PET in assessing nodal metastasis is reportedly 33-83%, but studies have shown the superiority of PET to CT and EUS for determining the N status while PET is more sensitive than CT for the detection of distant metastases.

Chapter 90

THE ROLE OF IMAGING IN GASTRIC SURGERY

***Efstathios Kotidis*, Manos-Georgios Pramateftakis
and Nikolaos Michalopoulos***

Department of Surgery, Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT

The esophagus is an integral part of the digestive system. There is a wide range of diseases (congenital, functional, structural, trauma and neoplasia) affecting the stomach, and as a result knowledge of the most current imaging technology is critical for accurate diagnosis and a successful management. This chapter will present the various imaging modalities and discuss their advantages and disadvantages.

INTRODUCTION

The stomach lies between the oesophagus and the duodenum in the upper abdomen. It is divided into four distinct regions. The cardia, which is the area that receives the oesophagus (gastro-oesophageal junction); the fundus, which is formed by the upper curvature; the body, the main central region of the organ; and the pylorus (antrum), which represents the lower section of the stomach that facilitates emptying into the small intestine (Image 1).

Entry of food into the stomach is controlled by the lower esophageal sphincter and exit from the stomach by the pyloric sphincter. These are under the control of several mechanisms including stimulant (parasympathetic) and inhibitory (orthosympathetic) control from the anterior gastric, posterior, superior and inferior coeliac and myenteric nerve plexuses.

The inner mucosal surface has many rugal folds that act to increase the surface area of the stomach lining and increase its efficiency.

Its arterial supply is provided by the right gastric artery (inferior lesser curvature), the left gastric artery (superior lesser curvature and cardia), the right gastroepiploic artery (inferior greater curvature), the left gastroepiploic artery (superior greater curvature) and the short

* Corresponding Author's Email: skotidis@gmail.com.

gastric vessels (fundus). Regarding the venous drainage, the left and right gastric veins drain to portal vein, the short gastric vein and left gastroepiploic vein drain to splenic vein and the right gastroepiploic vein drain to superior mesenteric artery. Lymphatics drain with arteries to the coeliac lymph nodes.

The gastric wall is composed of four layers: the mucosa includes the internal layer of epithelium the lamina propria and the muscularis mucosae; the submucosa which is a fibrous layer of connective tissue under the mucosa; the muscularis externa which is composed of three muscular layers (inner oblique, middle circular and outer longitudinal); and the serosa, the outermost layer of the stomach wall consisting of connective tissue which is continuous with the peritoneum.

The stomach wall contains several different types of glandular tissue. The cardia, fundus and pylorus all have different types of glands and are composed of a variety of different cells:

- Mucous cells: secrete a mucus gell layer and are found throughout the stomach [1, 2]
- Parietal (oxyntic) cells: secrete gastric acid and intrinsic factor throughout the stomach
- Chief (zymogenic) cells: secrete pepsinogen and rennin in the fundus only
- Enteroendocrine (APUD) cells: secrete a variety of products and are found throughout the stomach

C = cardia, G = fundus, B = body, A = antrum, D = duodenum.

GASTRIC DIVERTICULUM

The gastric diverticulum is a sac-like projection usually originated from the gastric fundus, located usually 1-2cm below the gastroesophageal junction.

It is the least common among gastrointestinal diverticula. The incidence varies from 0.01% to 0.11% at endoscopy studies. It is usually asymptomatic and, in some cases, could presents as a vague sensation of fullness immediately after meals or as gastric discomfort. Complications like ulceration, perforation, torsion, hemorrhage and malignancy are rare and an indication for surgical treatment [3].

Gastric diverticulum may be congenital (true diverticula that have all layers of the gastric wall) or acquired (false diverticula) and arise virtually anywhere along the stomach.

In imaging studies gastric diverticulum could mimic an adrenal mass. Surgical resection is recommended when the diverticulum is large, symptomatic or complicated [4].

Radiographic Features

A well defined saccular collection of barium protracting from the gastric wall is seen in barium swallow test (Image 2). CT scan may be needed and it shows a well defined saccular collection of fluid or gas, being filled by the iodinated oral contrast, demonstrating communication with the gastric cavity.

Image 2. Gastric diverticulum in the posterior wall of the cardia.

GASTRIC VOLVULUS

Gastric volvulus is a rare clinical entity defined as an abnormal rotation of the stomach of more than 180°, creating a closed-loop obstruction that can result in incarceration and strangulation. Borchardt described the classic triad associated with gastric volvulus: severe epigastric pain, retching without vomiting, and inability to pass a nasogastric tube [5].

Classification

The most frequently used classification system of gastric volvulus relates to the axis around which the stomach rotates, including organoaxial, mesentericoaxial, and combined.

Organoaxial type: In an organoaxial gastric volvulus, the stomach rotates around an axis that connects the gastroesophageal junction and the pylorus. The antrum rotates in opposite direction to the fundus of the stomach. This is the most common type of gastric volvulus and it is usually associated with diaphragmatic defects. Strangulation and necrosis commonly occur with organoaxial gastric volvulus.

Mesentericoaxial type: The mesentericoaxial axis bisects the lesser and greater curvatures. The antrum rotates anteriorly and superiorly so that the posterior surface of the stomach lies anteriorly. The rotation is usually incomplete and occurs intermittently. Vascular compromise is uncommon. Patients with mesentericoaxial gastric volvulus usually present without diaphragmatic defects and usually have chronic symptoms.

Combined type: The combined type of gastric volvulus is a rare form in which the stomach twists mesentericoaxially and organoaxially. This type of gastric volvulus makes up the remainder of cases and is usually observed in patients with chronic volvulus.

According to etiology, gastric volvulus can be classified as either type 1 (idiopathic) or type 2 (congenital or acquired).

Type 1: Idiopathic gastric volvulus comprises two thirds of cases and is presumably due to abnormal laxity of the gastrosplenic, gastroduodenal, gastrophrenic, and gastrohepatic ligaments. This allows approximation of the cardia and pylorus when the stomach is full, predisposing to volvulus. Type 1 gastric volvulus is more common in adults but has been reported in children.

Type 2: Type 2 gastric volvulus is found in one third of patients and is usually associated with congenital or acquired abnormalities that result in abnormal mobility of the stomach. The most common causes of gastric volvulus in adults are diaphragmatic defects.

Symptoms

Symptoms of gastric volvulus may range from mild abdominal pain and vomiting, when no or partial outlet obstruction is present, to severe pain and retching, when there is complete obstruction and ischemia.

Fiberoptic endoscopy has a limited role in the diagnosis of gastric volvulus because the twist precludes passage of the endoscope [6].

Radiographic Features

Typically, the first examination to be performed in the patient with symptoms referable to the chest and/or abdomen is a plain radiograph. Plain radiography may demonstrate findings that are indistinguishable from those that are produced by other causes of gastric atony or obstruction. In mesenteroaxial volvulus, the distended stomach appears spherical on supine images. Two air-fluid levels are visible on the upright film: 1 in the fundus, which is inferior, and 1 in the antrum, which is superior. Organoaxial volvulus is difficult to diagnose on plain images. The stomach lies horizontally and contains a single air-fluid level on upright views. No characteristic beak is observed. However, the modality is useful for excluding other causes of the patient's symptoms, such as pneumoperitoneum or pneumothorax.

Although this is a good examination to start with, the most definitive study is the upper GI barium study. Barium study is highly sensitive and specific. It is generally considered to be the criterion standard for diagnosis (Image 3). However, the diagnosis may be missed in cases of intermittent torsion. The upper GI series may show only a paraesophageal hernia during a symptom-free interval, leading to a false-negative diagnosis.

CT scanning and MRI are not typically considered to be the diagnostic examinations of choice in patients who are evaluated for gastric volvulus. However, the multiaxial reconstructions that are afforded by helical CT in particular may be preferred to the images obtained with conventional barium study, particularly in the acutely ill patient who is unable to tolerate a fluoroscopic examination. In addition, chronic gastric volvulus is often discovered incidentally in patients undergoing CT scanning for an unrelated condition.

Ultrasonography as a technique for the detection of gastric disease (and of gastric volvulus in particular) is still in its infancy. Angiography is often used in the evaluation of massive or refractory GI hemorrhage. Although it is a rare cause of such hemorrhage, gastric volvulus should be considered. The angiographic appearance is sensitive and specific during an acute episode.

Image 3. Double contrast swallow test illustrating mesentericoaxial gastric volvulus.

MENETRIER DISEASE

Ménétrier disease (MD) is a form of rare idiopathic hypertrophic gastropathy. The exact aetiology is not well known. The juvenile form has been linked to cytomegaloviral infection and usually resolves spontaneously. The adult form tends to progress with time and TGF- α activation of the EGFR receptor has been implicated. The characteristic of the disease is gastric mucosal hypertrophy, which may cause the rugae to resemble convolutions of the brain. Rugal thickening is predominantly caused by the expansion of the epithelial cell compartment of the gastric mucosa.

It most commonly affects the gastric fundal region also any part of the stomach may be involved. Achlorhydria, hypoproteinaemia and oedema comprise the classic triad. It is thought to be caused by protein-loss in the digestive system, protein-losing enteropathy. Acid production may be compromised. Hypoproteinaemia may lead to ascites and pleural effusions. Imaging differential considerations for diffuse rugal thickening include gastric lymphoma, which may also occur as part of post transplant lymphoproliferative disorder affecting the stomach and other forms of gastritis (infective gastritis, radiation gastritis, eosinophilic gastritis). Treatment includes high protein diet to correct hypoproteinaemia, PPI to treat attendant gastritis, EGFR monoclonal antibody (Cetuximab) or gastrectomy.

Radiographic Features

On fluoroscopy MD is usually characterised by giant rugal folds (Images 3, 4). On contrast-enhanced CT images, the thickened rugae appear as areas of thickened mucosa that project into the gastric lumen to a degree that may resemble convolution of brain [7].

Image 4. Menetrier's disease. The arrows indicate the hypertrophic mucosal folds.

Image 5. Barium swallow test in a patient with Menetrier's disease.

PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD) encompasses a number of entities, united by the presence of mucosal ulceration secondary to the effects of gastric acid. Since the recognition of *Helicobacter pylori* as a common causative agent, and the development of powerful anti-acid medications, peptic ulcer disease has become comparatively rare in western populations.

Generally peptic ulcer disease is encountered more frequently in males (M:F 3:1) and usually in the older population.

Risk factors include *Helicobacter pylori* infection, NSAIDs, corticosteroids, severe physiological stress/illness (e.g., admission to intensive care) and Zollinger-Ellison syndrome. The majority of cases are due to infection with *Helicobacter pylori*.

This can be confirmed with biopsies obtained at endoscopy and urea breath test, the combination of the two resulting in a detection rate of close to 100% [8]. Gastric and duodenal ulcers usually cannot be differentiated based on history alone, although some findings may be suggestive.

Epigastric pain is the most common symptom of both gastric and duodenal ulcers. It is characterized by a gnawing or burning sensation and occurs after meals—classically, shortly after meals with gastric ulcer and 2-3 hours afterward with duodenal ulcer. A peptic ulcer may present acutely as upper gastrointestinal bleeding (14%), perforation (6%) or gastric outlet obstruction (1%). Upper GI endoscopy is the preferred diagnostic test in the evaluation of patients with suspected PUD. Endoscopy provides an opportunity to visualize the ulcer, to determine the presence and degree of active bleeding, and to attempt hemostasis by direct measures, if required.

Endoscopy should be performed early in patients older than 45-50 years and in patients with associated so-called alarm features. When dyspeptic symptoms lead to identification of upper gastrointestinal ulceration (usually via endoscopy) patients are typically treated with acid lowering medications and tested for *Helicobacter pylori*, which if found is then eradicated.

This is important not only to prevent recurrence of peptic ulceration and reflux oesophagitis but also because it is associated with a number of malignancies including B-cell lymphoma and gastric adenocarcinoma [8].

Radiographic Features

Although historically barium studies were the mainstay of investigation for suspect peptic ulceration, endoscopy has in most centres largely replaced the barium meal. Many current younger radiologists have rarely if ever performed a full diagnostic barium meal, and the 'art' of this examination is gradually being lost. Barium meals are performed with liquid barium and an effervescent to distend the stomach with gas and allow a 'double contrast' image (Images 6, 7). Features of ulceration include pocket of barium filling the ulcer crater (85% round; 15% linear) and radiating folds of mucosa away from the ulcer. 10-15% of ulcers are multiple while postbulbar ulcers should raise the possibility of Zollinger-Ellison syndrome especially if ulcers are multiple and gastric folds are thickened.

Image 6. Benign gastric ulcer.

Image 7. Benign gastric ulcer.

In patients presenting acutely, a chest radiograph may be useful to detect free abdominal air when perforation is suspected (Image 8). However, even in the acute setting CT is the modality of choice for assessing a patient with acute abdominal pain, especially in cases where plain chest x ray fails to demonstrate the presence of free intra-abdominal air. In some settings, CT scan may be able to identify the site of bleeding prior to endoscopy. Haemorrhage, though, is challenging to identify and requires a multi-phase scan without positive oral contrast (typically non-contrast, arterial and delayed phase scans are obtained) and the presence of active bleeding. Extravasation and pooling/accumulation of contrast into the lumen of the bowel may be seen. Angiography may be necessary in patients with a massive GI bleed in whom endoscopy cannot be performed. An ongoing bleeding rate of 0.5 mL/min or more is needed for the angiography to be able to accurately identify the bleeding source. Angiography can depict the source of the bleeding and can help provide needed therapy in the form of a direct injection of vasoconstrictive agents [6, 8].

BENIGN GASTRIC TUMORS

With the advent of modern techniques and the widespread use of gastric endoscopy, benign gastric wall lesions are now diagnosed more frequently and can be studied using the tissue obtained by biopsy or polypectomy.

Image 8. Chest x-ray demonstrating free subphrenic air collection secondary to perforation of peptic ulcer.

All layers of the stomach wall have the potential to produce tumorous growths. In 40% of patients with benign gastric tumors, the lesions are mucosal tumors. Another 60% are nonmucosal based. Gastric polyps are defined as luminal lesions projecting above the plane of the mucosal surface and are relatively frequent in routine pathology practice.

Various subtypes of gastric polyps are recognized and divided into nonneoplastic and neoplastic and are also further classified by their association with polyposis syndromes [9].

Mucosal tumors are divided into nonneoplastic and neoplastic polyps.

Not neoplastic polyps include could either associated with polyposis syndrome (Peutz-Jeghers, juvenile polyps, Cowden disease, Cronkhite Canada syndrome, Gardner syndrome) or not associated with polyposis syndromes (hyperplastic polyps, inflammatory polyps, ectopic pancreas). Neoplastic polyps include fundic gland polyps, adenomatous polyps and gastric carcinoids [9, 10].

Nonmucosal tumors could be mesenchymal (GIST, lipoma, fibroma, glomus tumor) or vascular (hemangioma or lymphangioma). Many tumors are found incidentally on gastroscopy. Small tumors are usually asymptomatic, but larger tumors can ulcerate and cause occult bleeding and anemia. Large antral tumors cause intermittent gastric outlet obstruction. If ulcerated, these tumors may cause epigastric pain similar to a peptic ulcer.

Radiographic Features

Air-contrast studies of the stomach are sensitive in delineating mucosal details and lesions (Image 9). Lesions are often found incidentally by computerized tomography scan or other radiological evaluations of the upper gastrointestinal tract (Image 10).

Image 9. Double contrasts swallow illustrating a leiomyoma of the stomach.

Image 10. CT scan in the same patient as in image 9.

Endoscopy however is the procedure of choice for both diagnostic and therapeutic purposes. If small superficial lesions are removed endoscopically, follow-up should include a regular annual endoscopy. Endoscopic biopsies are difficult to interpret and may be misleading because deep layers of the stomach wall or the tumor are not sampled. Snare biopsies that retrieve the whole specimen are preferred whenever technically possible. Endoscopic ultrasound (EUS) is helpful in broad-based lesions, where the relationship of the tumor to the layers of the stomach is important (Image 11). Disruption of the normal sonographic appearance of 5 layers on EUS may signify invasion [11].

GASTRIC CARCINOMA

Gastric cancer is the second most common cause of cancer-related death in the world, and it remains difficult to cure, primarily because most patients present with advanced disease. In most developed countries, however, rates of stomach cancer have declined dramatically over the past half century.

Image 11. EUS in a patient with gastric GIST.

Decreases in gastric cancer have been attributed in part to widespread use of refrigeration and therefore decreased contamination of food by carcinogenic compounds arising from the decay of unrefrigerated meat products as well as decreased intake of salt. Another reason is the lower rates of chronic *Helicobacter pylori* infection, thanks to improved sanitation and use of antibiotics, and increased screening in some countries [12].

Adenocarcinomas account for approximately 95% of all malignant gastric neoplasms. The remaining 5% of tumors are lymphomas, leiomyosarcomas, carcinoids, or sarcomas.

Early disease has no associated symptoms; however, some patients with incidental complaints are diagnosed with early gastric cancer. Most symptoms of gastric cancer reflect advanced disease. Patients may complain of indigestion, nausea or vomiting, dysphagia, postprandial fullness, loss of appetite, melena, hematemesis, and weight loss [13].

Late complications include pathologic peritoneal and pleural effusions; obstruction of the gastric outlet or the gastroesophageal junction. Other symptoms may include intrahepatic jaundice caused by hepatomegaly; extrahepatic jaundice; and inanition resulting from starvation or cachexia of tumor origin. The differential diagnosis can be broad and includes gastric lymphoma, gastric metastasis, gastric stromal tumour (GIST), gastritis, benign gastric (peptic) ulcer, Menetrier disease, secondary changes from pancreatitis (from extrinsic inflammatory change). Endoscopy and biopsy (at least 6 samples) of any gastric lesion is the cornerstone in the diagnosis of gastric cancer. Esophagogastroduodenoscopy has a diagnostic accuracy of 95%. In selected cases, endoscopic ultrasound may be helpful in assessing depth of penetration of the tumor or involvement of adjacent structures. Depending on the depth of tumor invasion into the gastric wall, gastric adenocarcinoma is divided into early, if the tumor invades no more deeply than the submucosa, irrespective of lymph node metastasis and advanced if the tumor invades deeper than the submucosa [14].

Radiographic Features

Radiological methods are often the initial examination that raises suspicion for gastric carcinoma, besides being used in the staging of the disease.

Single-contrast barium studies have an overall sensitivity of 75% in the detection of gastric cancer, but double-contrast barium examinations have a sensitivity of 90-95% in gastric cancer detection, comparable to that of endoscopy (Images 12, 13). Double-contrast upper GI series and barium swallows may be helpful in delineating the extent of disease when obstructive symptoms are present or when bulky proximal tumors prevent passage of the endoscope to examine the stomach distal to an obstruction.

Image 12. Fluoroscopy test demonstrating gastric carcinoma.

Image 13. Fluoroscopy test demonstrating linitis plastica.

Depending on the fluoroscopy findings, early gastric cancer is divided into three types.

type I: elevated lesion, protrudes > 5 mm into lumen (polypoid)

type II: superficial lesion (plaque-like, mucosal nodularity, ulceration)

type III: shallow, irregular ulcer crater with adjacent nodular mucosa and fusion or amputation of radiation folds.

Likewise, advanced gastric cancer may be polypoidal, ulcerative, or infiltrating lesions on barium studies.

With ulcerated carcinomas, an irregular crater is located in a ring of malignant tissue. Infiltrating carcinomas result in irregular narrowing of the stomach, with nodularity or spiculation of the mucosa. Submucosal spread of tumors may result in pseudoachalasia or secondary achalasia with tapered, beaklike narrowing of the distal esophagus and infiltration of the gastric cardia. Ultrasound is not useful, unless a large epigastric mass is present or on endoscopic ultrasound study.

CT is currently the staging modality of choice because it can help identify the primary tumor, assess for local spread, and detect nodal involvement and distant metastases.

Additionally, CT is used to monitor a patient's response to treatment. Detection of gastric carcinoma is improved by using thin-section sequences and helical CT (14, 15). The early arterial phase is used to assess enhancement of the gastric wall; the later portal venous phase is used to assess the liver parenchyma for metastases. CT scans may show polypoidal mass with or without ulceration, focal wall thickening with mucosal irregularity or ulceration, wall thickening with the absence of normal mucosal folds (infiltrative lesions), focal infiltration of the gastric wall, variable thickening of the wall and marked contrast enhancement (typical of scirrhous lesions). Finally, mucinous carcinomas have low attenuation due to their high mucin content and which may contain calcification.

The depth of tumor invasion is not accurately assessed with CT. Tumor invasion of the perigastric fat is seen as soft-tissue stranding. Tiny 4- to 8-mm nodules may be observed. These may coalesce into sheets of tumor in advanced cases. Overall, the accuracy of determining the T-stage with CT is approximately 66%. CT depicts 75% of nodes larger than 5 mm in diameter, but it does not depict tumor in normal-sized nodes. CT is not useful in distinguishing between enlarged nodes due to reactive changes and those due to tumor. Because the portal vein drains the stomach, the liver is the most common site for hematogenous metastases (see the first image below).

Less common sites are the lungs (see the second image below), adrenal glands, and kidneys. Bony and cerebral metastases are uncommon. Intraperitoneal and omental metastases are common in advanced gastric cancer. They consist of nodules, localized fluid collections, and irregular thickening and stranding of the mesentery and omentum. Ascites and small-bowel obstruction may occur. Gastric carcinoma is the most common primary tumor to metastasize to the ovaries. These ovarian metastases are usually bilateral and are known as Krukenberg tumors. CT may fail to depict tiny omental and peritoneal deposits; small pelvic deposits may be overlooked as well [11-13].

MRI studies in which a breath-hold, fast-imaging technique and water were used showed accuracy rates comparable to those of helical, biphasic CT scanning. In T staging, the accuracy of MRI is 73%, compared with 67% for CT. In N staging, the accuracy of MRI is 55%, compared with 59% for CT. EUS has improved the accuracy of local staging of gastric

carcinomas. Unlike CT and MRI, EUS can depict individual layers of the gastric wall, with a rotating high-frequency probe inserted via an endoscope.

Image 14. CT scan illustrating thickening of the gastric wall because of adenocarcinoma of the antrum.

Image 15. CT scan in a patient with gastric outlet obstruction secondary to gastric cancer.

The gastric wall is visualized as 5 concentric bands: Mucosa – Echogenic, Muscularis mucosa – Hypoechoic, Submucosa – Echogenic, Muscularis propria – Hypoechoic and Serosa – Echogenic.

A gastric tumor is demonstrated as a hypoechoic mass with varying mural invasion. Regarding N staging, involved nodes are rounder and more hypoechoic than normal nodes. However, EUS is limited to an area 5 cm from the probe. It cannot be used to assess distant metastases or nodes more than 5 cm away from the probe. Intraoperative US and laparoscopy have an accuracy of 81% in T staging and an accuracy of 93% in N staging; however, the necessary equipment and expertise are not widely available.

PET scanning may be useful in the staging and postoperative assessment of gastric carcinomas. The only limitation of PET is that involved local lymph nodes cannot be separated from the primary tumor. Thus, its role in N staging is limited [15].

GASTRIC LYMPHOMA

Gastric lymphoma may either represent secondary involvement by systemic disease or primary malignancy confined to the stomach. Primary gastric lymphoma is an uncommon condition accounting for about 2% of all lymphomas. It is the most common source of lymphomas in the gastrointestinal tract. Typically primary gastric lymphoma occurs in adults in the 6th decade of life, without gender predilection. Secondary gastric lymphoma matches the demographics of the underlying lymphoma [16]. Patients usually present with long standing epigastric pain and/or dyspepsia which is attributable to *Helicobacter pylori* rather than the lymphoma *per se*. Three distinct types of gastric lymphoma are recognised:

- low-grade MALT lymphoma, accounting for 60% of all primary gastric lymphomas
- primary sporadic lymphoma, the vast majority of which are B-cell non-Hodgkins lymphoma
- secondary involvement of the stomach by systemic lymphoma

Mucosa-associated lymphoid tissue (MALT) lymphoma are strongly associated with *Helicobacter pylori* (85-98% of cases). These are low-grade lymphomas and may regress following treatment of *Helicobacter* infection. It is very important to differentiate gastric lymphoma from gastric adenocarcinoma and GIST since the treatment of lymphoma is primarily chemotherapy. Subtotal gastrectomy, with post-operative chemotherapy is undertaken in refractory cases, or in the setting of complications, including gastric outlet obstruction [17].

Radiographic Features

Appearances in barium swallow vary from normal, to grossly abnormal. Possible appearances include bull's eye appearance due to central ulceration, filling defects, thickened gastric rugae or linitis plastica. On CT scan, gastric lymphomas typically present with marked thickening of the gastric wall with extensive lateral extension of the tumour representing its submucosal spread. In some instances the submucosal spread involves nearly all the stomach, mimicking linitis plastica. In such cases, mural involvement may even extend across the pylorus into the duodenum or superiorly into the oesophagus. The mass is usually homogeneous in attenuation, but may contain focal areas of low density representing necrosis. Extensive retroperitoneal and local nodal enlargement is often seen.

Endoscopic ultrasound with EUS needle biopsy may be necessary to diagnose and to stage the disease. Hematological parameters are usually checked to assist with staging and to exclude concomitant leukemia [16, 17].

ABSTRACT

In this chapter, we examine the various imaging modalities used to evaluate the genitourinary (GU) tract. Advances in imaging technology have improved the clinical practice of urology and continue to be an active area of growth. Imaging modalities used by urologists include plain film radiography, ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), radionuclide studies, and positron emission tomography (PET). Each modality plays an important role in the diagnosis and management of urologic diseases and when used appropriately, provides cost-effective care. This chapter explores indications for these modalities and their optimal use.

Keywords: imaging, urology, uro-radiology

PLAIN FILM RADIOGRAPHY

1. The Kidneys, Ureters, and Bladder (KUB) Film

Summary: Plain film abdominal radiographs are frontal, supine radiographs of the abdomen that capture the kidneys, ureters, and bladder and are often called KUBs. The KUB may be used as a primary study or as a scout film in anticipation of the use of contrast media [1]. In urology, KUBs are often used in the diagnosis of renal calculus disease and to assess

* Corresponding Author's Email: mkim27@partners.org; Fax: 617-726-6131.

the positioning of indwelling devices such as ureteral stents [1]. They are more commonly used to investigate the etiologies of non-GU processes such as bowel obstructions or bony fractures that may indicate the presence of urologic injuries. Because of the advent of the CT scan, use of the KUB has become limited. Nonetheless, it remains a cost-effective tool for monitoring residual stone burden after therapy for urolithiasis.

Technique: Placement of the patient is in the supine position [1]. The radiograph is obtained using an anterior-to-posterior (AP) exposure and should include the diaphragm superiorly and the pubic symphysis inferiorly. Oblique films may be used to aid in visualization and to clarify the location of peritoneal structures relative to the GU tract.

Limitations: The sensitivity of the KUB for the detection of uroliths can be adversely affected by overlying stool, bowel gas, or bony structures [1]. Non-GU calcifications in the pelvic veins or other vascular structures may also be confused with ureteral calculi. Poorly calcified, uric acid, or indinavir stones may be radiolucent and therefore not visualized. The KUB is also of limited use for evaluating soft tissue abnormalities.

Figure 1. Kidneys, ureters, and bladder (KUB) film.

2. Intravenous Urography (IVU)

Summary: IVU is used to demonstrate abnormalities of the renal collecting system, ureters, and bladder. IVU is widely considered obsolete and has now been replaced by US, CT, and MRI in most developed countries. In resource poor healthcare systems, an important indication for IVU is the investigation of renal and ureteral anatomy in the setting of suspected obstruction (i.e., secondary to nephrolithiasis or following surgery). IVU is also indicated for patients with unexplained hematuria to diagnose the presence of tumors or other anatomical abnormalities. IVU can also be used in the operating room to opacify the collecting system during extracorporeal shock wave lithotripsy (ESWL), to facilitate access during percutaneous nephrolithotomy (PCNL), or to assess renal trauma burden intraoperatively in trauma patients with suspected renal injuries who did not undergo preoperative imaging.

Technique: A bowel prep may be needed to facilitate the visualization of the ureters and upper collecting system [1]. Placement of the patient is in the supine position. A scout KUB

is taken to confirm correct positioning and exposure. A 50 to 100 mL bolus of contrast is injected. The nephrogenic phase radiograph is captured almost immediately after injection as the contrast is excreted from the bloodstream. Additional films are taken at five-minute intervals based on the clinical scenario. Abdominal compression and oblique views may be used to better visualize the ureters and to precisely differentiate ureteral stones from pelvic calcifications. Post-void films are obtained to evaluate for the presence of bladder outlet obstruction, or bladder-filling defects such as stones or malignancies.

Limitations: IVU has been largely replaced by CT and MRI for other diagnostic purposes given that they provide greater anatomic detail and three-dimensional reconstructions.

3. Retrograde Pyelography

Summary: Retrograde pyelography is a procedure in which contrast is injected into the upper urinary tract in a retrograde fashion to opacify the ureters and collecting system [1]. Retrograde pyelograms help identify filling defects (e.g., stones, tumors) and delineate renal anatomy in preparation for surgery. It is commonly used intraoperatively to opacify or to distend the collecting system to assist in percutaneous access of the kidney, ureteroscopy, or stent placement. Similar to an IVU, the retrograde pyelogram can also play a role in the workup of hematuria, in the surveillance of urothelial carcinoma, and in the evaluation of traumatic or iatrogenic injury to the ureter or collecting system. In children, retrograde pyelograms are indicated for evaluation of congenital or acquired ureteral obstruction and for elucidation of deformities of the ureters or intrarenal collecting system.

Figure 2. Retrograde pyelogram.

Technique: Retrograde pyelograms are performed with the patient under regional or general anesthesia [2]. The patient is placed in the dorsal lithotomy position. An abdominal plain film is initially obtained to ensure appropriate positioning. Cystoscopy is performed to visualize the ureteral orifice. A ureteral catheter or a cone tip catheter is inserted and contrast is injected into the upper urinary tract [1]. Contrast may be diluted to 50% with sterile saline to prevent subtle filling defects from being obscured. Care should be taken to prevent over-distension of the collecting system and contrast backflow, which can introduce infected urine

into the vascular system (by pyelolymphatic drainage) as well as systemic absorption of contrast media with resultant adverse systemic reactions. Retrograde pyelograms evaluate the upper urinary tract in real time and can be immediately interpreted as they are performed.

Limitations: Retrograde pyelography is difficult when the ureteral orifices cannot be properly identified or accessed [1]. Intravenous injection of methylene blue or indigo carmine (indigotindisulfonate sodium) can be used to identify the orifices. If trauma and extravasation of contrast occurs extraluminally, it is generally without serious complication. However, if large quantities of urine continue to extravasate, a stent may be indicated [2]. Retrograde pyelography should not be done in the setting of a urinary tract infection to avoid the risk of pyelonephritis and bacteremia.

4. Retrograde Urethrography

Summary: A retrograde urethrogram (RUG) is used to evaluate the integrity and anatomy of the anterior and posterior urethra [3]. It is essential for the diagnosis of urethral injury or stricture. RUGs are beneficial for demonstrating the length of a stricture when it cannot be determined by direct visualization. They can also show anatomy distal to a stricture that may not be readily visualized by voiding cystourethrogram. RUGs are also commonly used if there is suspicion of a foreign body or urethral trauma with additional clinical findings such as blood at the meatus, gross hematuria, scrotal hematoma, or high-riding prostate by digital rectal examination. If urethral injury is suspected, a RUG should be performed before placing a Foley catheter. If urethral disruption is observed, a suprapubic tube (SPT) would be preferred.

Figure 3. Retrograde urethrogram.

Technique: The patient is supine in a slightly oblique position with the penis on stretch [1]. A small Foley catheter is placed in the fossa navicularis, just past the urethral meatus, and inflated with 2 mL of sterile water. Thirty mL of contrast is injected into the catheter and a plain radiograph is obtained. A penile clamp can be used to keep the contrast in the urethra if desired. If contrast leakage is present, it suggests urethral injury and may help to determine whether surgery is indicated.

Limitations: RUGs provide limited information about surrounding soft tissue injury.

5. Cystogram

Summary: A cystogram evaluates the anatomy of the bladder and provides information about its size, shape, and contour [3]. Cystograms aid in the evaluation of intravesical pathology such as diverticula, fistulas, and trauma. Filling defects may provide information about stones or tumors. They are also indicated for evaluating inguinal hernias involving the bladder, colovesical or colovaginal fistulas, anastomotic integrity after surgery, and blunt or penetrating bladder trauma. Last, cystograms with contrast can be useful for studies of urodynamics.

Technique: The patient is placed in the supine position. A catheter is placed in the bladder and filled with 200 to 400 mL of contrast under gravity at 30-cm height. Adequate filling is necessary to ensure visualization of bladder extravasation or intravesical pathology [1]. AP and oblique films are taken to assess for lesions, including posterior lesions, which may be obscured. The patient is instructed to void three times, after which post-void images are taken to evaluate the quantity of urine left behind. A final radiograph of the kidneys may be performed to evaluate for occult vesicoureteral reflux not seen during the procedure itself.

Figure 4. Cystogram.

Limitations: While the cystogram uses less radiation than a pelvic CT scan, it is less sensitive and specific for the diagnosis of most intravesical pathologies except the detection of bladder rupture [1].

6. Voiding Cystourethrogram (VCUG)

Summary: A VCUG is used to visualize the anatomy of the urethra and bladder during micturition [2]. The exam is most commonly used in children with UTIs to assess for the presence of vesicoureteral reflux. VCUG is indicated for all boys with recurrent UTIs, boys with abnormalities on US after their first UTI, girls less than three years of age with their first UTI, girls less than five years of age with their first febrile UTI, older girls and women with pyelonephritis or recurrent UTIs, and in the setting of suspected bladder obstruction, trauma,

or rupture. VCUGs should be avoided in patients with untreated UTIs, contrast media hypersensitivity, or fevers within the past day.

Technique: The patient is placed in the supine or semi-upright position using a table capable of reaching the full upright position [2]. A pelvic plain film is obtained. In children, a 5 to 8 French (F) feeding tube is used to fill the bladder with contrast using patient comfort as a guide to determine the appropriate volume [1]. In adults, a standard catheter is placed and the bladder is filled with 200 to 400 mL of contrast. The catheter is removed and an AP film is obtained. The patient is instructed to void while additional AP and oblique films are taken. The bladder neck and urethra may be evaluated by fluoroscopy during voiding. Oblique views may demonstrate low grade reflux that cannot be captured on an AP film. The exam ends when the patient voids while the radiologist is watching under fluoroscopy. Consumption of fluid promotes excretion of contrast media after the procedure. It is important to watch the contrast during voiding, as this is when the bladder has the most pressure and when reflux will most likely occur.

Figure 5. Voiding cystourethrogram.

Limitations: A VCUG requires filling the bladder with a catheter, which is difficult in children and in patients with anatomic abnormalities of the urethra or bladder neck [1]. Bladder filling may lead to autonomic dysreflexia in patients with spinal cord injuries and stimulate bladder spasms in some patients.

ULTRASONOGRAPHY

US uses the mechanical properties of sound to provide real-time images and is commonly used in urology for diagnosis, interventional management, and longitudinal follow up [3]. US is inexpensive, portable, and radiation-free. However, its specificity depends on the skill level of the operator and the body habitus of the patient.

1. Renal US

Summary: Renal US provides a cost-effective method of investigating renal lesions. A curved array transducer of 3.5 to 5.0 MHz is used in adults; higher frequencies can be used in children [1]. Intraoperative renal US during open or laparoscopic cases typically employs a linear transducer of 6 to 10 MHz given the physical proximity of the organ. Renal US is indicated for the assessment of renal and perirenal masses; upper GU tract dilation; flank pain during pregnancy; hematuria in patients who are not candidates for other imaging modalities; or impaired renal function. Renal US may also be used for interventional procedures such as renal biopsies, renal mass ablation, or nephrostomy tube placement. Vascular abnormalities including renal artery stenosis, renal vein thrombosis, arteriovenous fistulas, and pseudoaneurysms can also be detected by renal US with Doppler concurrent imaging.

Technique: US of the right kidney is performed with the patient supine. The kidney is located in the mid-clavicular line in the right upper quadrant [1]. The transducer is moved laterally until the mid-sagittal plane of the kidney to visualize the anterior and posterior kidney. The probe is rotated 90 degrees counter clockwise and the kidney is imaged in the transverse plane which includes visualization of the renal hilum. Imaging of the left kidney is similar except that it is slightly more cephalad due to the absence of the liver. It is more difficult to image due to interference from bowel gas from the splenic flexure and because the liver does not provide an acoustic window. Echogenic renal lesions include renal stones, angiomyolipomas (AMLs), renal cortical neoplasms, abscesses, and hematomas.

Figure 6. Renal ultrasound.

Limitations: Obesity, intestinal gas, and physical deformity are limitations to adequate US imaging studies [1]. Renal US is excellent for diagnosing benign renal lesions such as cysts, but has poor sensitivity for renal masses less than 2 cm as well as for masses other than angiomyolipomas (AML). More complicated lesions require correlation with another imaging modality, most commonly a CT scan.

2. Transabdominal Pelvic US

Summary: Transabdominal pelvic US, commonly referred to as bladder US, is used to image the lower GU tract in men and women [3]. Common indications for transabdominal pelvic US include assessment of bladder volume, post-void residual, bladder wall configuration and thickness, prostate size and morphology, and catheter placement. A curved array transducer is used. Of note, handheld BladderScan™ devices used in the clinic and wards for measuring bladder volumes and post-void residuals are based on US technology.

Technique: The patient is positioned supine. The bladder is moderately distended to ensure appropriate visualization. The bladder is scanned in the sagittal and transverse planes angling the probe into the pelvis to visualize the bladder beneath the pubic bone [1]. To visualize the prostate, the transducer is fanned inferiorly until the largest transverse diameter of the prostate is identified. Measurements of the width and height are obtained. The transducer is rotated 90 degrees clockwise to produce a true sagittal image of the prostate, which is again measured. Detection of hypertrophy or an enlarged median lobe should be noted to provide additional information regarding the length, size, and configuration of the prostatic urethra and median lobe. These data may provide secondary information about the etiology of bladder outlet obstruction.

Limitations: An under-distended or empty bladder will interfere with the identification of distal ureteral or bladder obstructions, stones, or tumors, and with the assessment of prostatic morphology.

3. Scrotal US

Summary: Scrotal US is an excellent tool for investigating intratesticular and extratesticular disease including testicular neoplasms, torsion, infection, and inguinal hernias [3]. It is commonly used with Doppler sonography to evaluate blood flow to provide detailed anatomic and physiologic information. Indications include assessment of scrotal or testicular mass, pain, or trauma. It may also be used in the infertility workup.

Figure 7. Scrotal ultrasound.

Technique: The patient is placed in the supine position with the scrotum supported on a towel. A high frequency linear array 6 to 12 MHz and 4 to 7.5 cm in width is used [1]. The sonographer starts with a sagittal view of testes from the midline medially and then laterally from the mid-transverse section to the upper and lower poles. The epididymis and scrotal contents are evaluated.

Limitations: The pathognomonic sign of torsion is the absence of intratesticular blood flow. Collateral blood flow may be preserved and it is important for the sonographer not to confuse its presence with that of intratesticular blood flow [1]. Imaging of the contralateral testis can be performed to confirm that the study is able to adequately detect intratesticular blood flow.

4. Penile US

Summary: Penile US is commonly used to assess the vascular supply of the penis for the diagnosis of erectile dysfunction secondary to arterial insufficiency and veno-occlusion etiologies. Moreover, penile US remains a mainstay for the diagnosis of traumatic injuries [1]. Penile US is also indicated for the evaluation corpora cavernosa fibrosis, urethral stricture or diverticulum, foreign body, priapism, and Peyronie's disease.

Technique: The patient is placed in the supine position. A 6 to 12 MHz linear array transducer is used to image the phallus in the longitudinal and transverse planes in a systematic fashion beginning at the base of the penis and proceeding distally to the glans [1]. Scanning the scrotum and perineum also allows for imaging of the proximal urethra and corporal bodies. Lubricating gels or intracavernosal injection of vasoactive substances may be useful for evaluating anatomy and vascular flow.

Limitations: Penile US has a limited sensitivity and specificity for the detection of penile arterial dysfunction. Pudendal arteriography may be needed to collect more definitive data prior to surgical intervention.

5. Transrectal US of the Prostate

Summary: Transrectal ultrasound (TRUS) allows for the visualization and evaluation of the prostate gland [3]. TRUS is used to guide prostate biopsy, to determine prostate volumes for brachytherapy and cryotherapy (e.g., by planimetry), and to evaluate benign prostatic hypertrophy (BPH). TRUS provides enough resolution to differentiate between the peripheral and transitional zones of the prostate so that the peripheral zone, in which cancers are more commonly located, can be targeted with the biopsy needle [1].

Technique: The patient is placed in left lateral decubitus position with the legs drawn inward [2]. A 6 to 10 MHz endorectal US probe is inserted into the rectum until it reaches the base of the prostate [1]. The probe is moved caudad to visualize the seminal vesicles, bladder neck, prostatic apex and proximal urethra. Complete evaluation of the prostate includes scanning in the sagittal and transverse planes, thoroughly inspecting the prostate for echogenic lesions, cysts, contour, and calcifications. The seminal vesicles and vas deferens should be fully visualized.

Limitations: The sensitivity and specificity of gray-scale TRUS is limited for the reliable detection of all cancers. Color and power Doppler imaging modes improve detection but biopsy remains the gold standard for diagnosis.

TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING MODALITIES

1. X-Ray Computed Tomography

Summary: CT is often the imaging modality of choice for the diagnosis and management of urologic diseases and has largely replaced other types of imaging as the first-line imaging for nephrolithiasis, hematuria, and workup of renal or urothelial masses [1]. CT scans have advantages over plain film radiographs in that they eliminate superimposition of images of structures that obscure the organ of interest. CT scans of traumatic injuries of the bladder can be complemented by cystogram to better assess the location of the rupture.

Technique: The patient is placed in the supine position on a gantry that passes through the center of CT scanner [5]. The length of study depends on the indication.

Limitations: Although CT scans are generally associated with greater radiation exposure than IVUs, a low-dose CT stone protocol with minimal radiation exposure can be used to detect renal calculi. CT scans sometimes require radiocontrast agents, which often are not without side effects, for improved visualization. Contrast induced nephropathy, which is more prevalent in patients with preexisting renal insufficiency, diabetes, or hypovolemia, should be avoided. Metal implants may create radiographic artifacts.

Figure 8. X-ray computed tomographic scan.

2. CT Urography

Summary: CT urography evaluates the entire GU tract using different phases of contrast enhancement [1, 3, 5]. Patients with hematuria and those presenting with flank or abdominal pain are often evaluated by CT urography.

1. The non-contrast phase scan provides an optimal set of images for detecting calcifications, and acts as a baseline for assessing the changes noted following contrast injection [5].
2. The arteriographic or early arterial phase scan is taken 20 seconds after contrast injection and evaluates arterial pathologies such as fibromuscular dysplasia or renal artery stenosis [3, 5].
3. The late arterial or corticomedullary phase is taken 40 seconds after contrast injection and allows for the detection of hypervascular renal masses [5]. This study should always be obtained when information about the renal vasculature is desired or if there may be an aneurysm, arteriovenous malformation, or fistula.
4. The nephrographic phase occurs 80 to 100 seconds after contrast injection and assesses the abdominal and pelvic viscera [5]. Non-hypervascular renal masses are best evaluated during this phase.
5. The excretory phase occurs two minutes after contrast injection and evaluates the collecting system [1, 5]. It is useful for evaluating hematuria and is more sensitive than retrograde pyelogram for detecting upper tract urothelial cancers.

Figure 9. Computed tomographic urogram.

Technique: CT urography may be performed supine or prone [5]. Prone images help to precisely identify the locations of distal ureteral-vesical junction stones. If there is concern that the stone is in the distal ureter, other signs of obstruction helpfully differentiate it from pelvic calcifications. Non-contrast and excretory phase images should span the diaphragm to the pubic symphysis to visualize the entire GU tract.

Limitations: CT urography is not as sensitive as cystoscopy for the detection of intravesical tumors and should not be a substitute in the evaluation of hematuria. However, it can identify filling defects in the bladder caused by larger tumors. In patients with recurrent need for radiation exposure, low-dose CT protocols may be used with minimal sacrifice of diagnostic capabilities.

3. Magnetic Resonance Imaging

Summary: MRI uses magnetic fields and radio waves to provide excellent soft tissue resolution and can be used in patients who cannot be given iodinated contrast [1, 3, 5]. MRI images may be weighted to show different anatomical structures. Fluids such as urine have low signal and appear dark in T1-weighted images. Intravenous gadolinium contrast can be used to augment the relaxation of protons in T1-weighted images, making the kidneys brighter and increasing the chance of detecting renal masses. Fluids in T2-weighted images have higher signal and appear bright. In the kidney, this causes the cortex to appear brighter than the medulla. Urine in the bladder is also bright on T2-weighted images. MRI can differentiate among complex renal cysts, which may be filled with heterogeneous material, in ways that CT or US cannot. Blood breakdown products due to hemorrhage result in high signal on T1-weighted images, whereas they result in black rings around cyst walls on T2-weighted images. MRI is often used to evaluate renal masses, staging of renal malignancies, as well as aid in the planning of surgery for RCC, particularly in the setting of renal vein or inferior vena cava (IVC) invasion [1, 3, 5]. Detectable lesions are assessed for increases in signal intensity by comparing non-enhanced to gadolinium-enhanced T1-weighted images. Adrenal evaluation by MRI is useful because of variations in tissue density among the various adrenal lesions.

Technique: The patient is placed in the supine position on a gantry that passes through the bore of the magnet [3]. More than 30 minutes are needed for the scanner and patients will need to hold their breath for 20 to 30 seconds during each imaging sequence. If the patient is noncompliant, the image will be compromised.

Figure 10. Magnetic resonance imaging scan.

Limitations: An important disadvantage of MRI is that patients must stay still for extended periods of time in enclosed environments [1]. If patients have difficulty with breath-holding, severe claustrophobia, pacemakers, sterile magnetic implants, retained magnetic foreign bodies, cochlear implants, neurovascular aneurysm clips, or cardiac defibrillators other imaging modalities are preferred. Gadolinium contrast agents should not be used in patients with renal insufficiency as it may lead to development of debilitating fibrosing dermopathy.

NUCLEAR MEDICINE

1. Positron Emission Tomography

Summary: PET allows for the detection of primary and metastatic cancers and for the determination of disease extent [4, 5]. PET is combined with high resolution CT to increase the detection of recurrent or metastatic cancers. For seminomas and nonseminomatous germ cell testicular tumors, PET/CT is more accurate than CT for staging of residual masses after chemotherapy [1]. PET/CT also has a promising role in clear cell RCC. The antibody cG250 recognizes carbonic anhydrase IX, which is related to unrestrained cancer growth, and positron-emitting radionuclide, iodine 124, has been successfully attached to it and injected into RCC patients. Other tracers are being developed for the detection of metastatic prostate cancer. Fewer studies have addressed the role of PET in bladder cancer.

Technique: Prior to the scan, a radioactive tracer isotope is injected into the blood [2]. After a waiting period during which the tracer becomes concentrated in the tissue of interest, the patient is scanned. Tissue concentrations are recorded as the tracer decays.

Limitations: The accuracy of PET can be compromised if it is performed within two weeks of completing chemotherapy due to decreased metabolism and increased macrophage activity. It is recommended that PET/CT be delayed for four to 12 weeks following chemotherapy [1].

2. Radioisotope Renography

Summary: Radioisotope renography plays an important role in providing information about kidney function [1, 5]. There are several commonly used agents in nuclear scintigraphy.

1. ^{99m}Tc -DTPA is used to evaluate obstruction and renal function. It is excreted through the kidney and requires a normal glomerular filtration rate (GFR) to provide accurate results.
2. ^{99m}Tc -DMSA, is cleared by filtration and secretion and localizes to the renal cortex. It is the standard test used to identify cortical defects and ectopic or aberrant kidneys, and can also differentiate between benign and malignant lesions.
3. ^{99m}Tc -MAG3, is cleared mainly through tubular secretion with approximately 10% cleared extra-renally. It is limited in its ability to measure GFR because it binds to plasma proteins. It is the study of choice to evaluate renal function and plasma flow

in individuals with impaired renal function and urinary obstruction and to evaluate anatomical abnormalities.

Figure 11. Radioisotope renogram.

Technique: The radioisotope is injected intravenously [1]. Gamma scintillation cameras measure radiation emitted from the radioisotope and digital workstations process and display the information. Of note, ^{99m}Tc -MAG3 works with diuretic scintigraphy to provide a differential of renal function and clearance time comparing the two kidneys. A diuretic, usually 0.5 mg/kg furosemide, is administered when maximum collecting system activity is visualized. The initial phase of the study is called the flow phase. Images are taken at 2-second intervals for two minutes. Images are taken at 1-second intervals for one minute. This phase demonstrates renal uptake, background clearance, and abnormal vascular lesions that may be due to AVM, tumors, or active bleeding. The second phase is called the renal phase. It is most useful for evaluating renal function. The time to peak uptake is typically between 2 and 4 minutes. During this phase, images are taken at 1-minute intervals for half an hour. In the last phase, the excretory phase, images are again taken at 1-minute intervals for half an hour. The half-life ($T_{1/2}$) is the time it takes for the collecting system activity to decrease by 50% from the time of diuretic administration. Transit time through the collecting system of less than 10 minutes is consistent with a normal, non-obstructed system [1]. A $T_{1/2}$ of 10 to 20 minutes represents a mild to moderate delay and may indicate the presence of a mechanical obstruction. A $T_{1/2}$ greater than 20 minutes is consistent with a high grade obstruction. If ureteral stents are in place, the patient should have an unclamped bladder catheter.

Limitations: For diuretic scintigraphy, the $T_{1/2}$ is highly technician dependent because the diuretic must be given when the collecting system displays maximum activity.

3. Whole-Body Bone Scintigraphy

Summary: Whole-body bone scans are the most sensitive method for detecting bone metastases from primary prostate and renal cancers [5].

Technique: The patient is injected with a radioactive tracer and then scanned with a gamma camera, a device that detects the radiation emitted [3].

Limitations: A positive bone scan is not specific for cancer and may prompt the use of other imaging modalities (e.g., plain film radiography, CT, or MRI) to confirm the findings and correlate them with any prior history of fracture, trauma, surgery, or arthritis. Bone scans can be mistaken as normal if there is uniformly increased uptake in the bony structures due to diffuse metastatic bony disease.

Chapter 92

THE ROLE OF IMAGING IN PLASTIC SURGERY

***Alexandros Mekras^{1,*}, MD, PhD
and Vasileios Kalles², MD, PhD***

²Naval and Veterans Hospital of Athens, Athens, Greece

ABSTRACT

From the era that Röntgen discovered X-rays, imaging studies have been a significant adjunct in the clinicians' armamentarium. The rapid development of modern imaging techniques, as well as the increased accessibility to sophisticated imaging techniques, has allowed physicians to have access to detailed anatomical and functional information. Plastic surgery, being one of the surgical specialties that uses the most up-to-date technologies in both diagnosis and treatment, is a field that modern imaging techniques have had a significant impact on. Current applications of imaging in plastic surgery range from staging of melanoma patients to preoperative submillimeter-scale planning of perforator flaps. Nearly all currently available imaging techniques, including X-rays, Ultrasound, Computed Tomography, Magnetic Resonance Imaging, and Positron Emission Tomography, are being used as adjuncts in the diagnosis and/or staging of plastic surgical conditions and diseases. Furthermore, as accurate preoperative planning of plastic and reconstructive surgical procedures has been shown to be of high importance for both the patient as well as the health system by improving the surgical outcomes, imaging techniques, and more specifically CT – and MRI – based studies, have emerged as the outstanding gold standard techniques.

INTRODUCTION

Over the past years, the field of imaging has seen continuous and increasingly rapid developments, regarding both the availability and the accessibility of imaging techniques. Imaging procedures nowadays integrate information strictly anatomical with high resolution

* Corresponding Author's Email: almekras@yahoo.gr.

images, and, in the case of molecular imaging, information on the functional nature of the tissue. All this detailed information allows plastic surgeons to have precise preoperative data that correlate with the clinical status of the patient.

As a result, imaging has become an essential part of preoperative planning for the patient undergoing a plastic surgical procedure, whether this should be reconstructive or aesthetic.

Apart from the classical applications of imaging in disease diagnosis and staging (such as skin melanoma), particular applications of preoperative imaging include perforator flap surgery and facial reconstruction, among others. It is now well established that accurate preoperative analysis can reduce the length of operations, enhancing the surgical design and minimizing unneeded dissections.

The modern imaging modalities that are now available can offer high-resolution, three-dimensional analysis of the vascular anatomy, and perfusion. Computed Tomography (CT) and magnetic resonance imaging (MRI) are the modalities that have lately been established as outstanding non-invasive techniques for the depiction of vascular and non-vascular systems.

This chapter will elaborate on the use and the importance of imaging techniques in plastic surgery, including the role of both CT and MR angiography, the techniques that are currently the state of the art in preoperative exploration of the vascular system.

1. DIAGNOSTIC IMAGING IN PLASTIC SURGERY

1.1. Skin Melanoma

Although skin melanoma accounts for only 5% of skin cancers, it represents nearly half of skin related deaths and globally, in 2012, melanoma occurred in 232,000 people and resulted in 55,000 deaths. Its prognosis is directly related to the clinical stage at presentation, and patients with metastatic disease survive for a median of 6-10 months (Table 1) [1, 2].

Melanoma can disseminate to virtually any organ of the human body, but has a predilection for the regional lymph nodes, liver, lung and brain [3]. Surgery remains the cornerstone of melanoma treatment, while imaging plays a key role in preoperative staging and postoperative follow – up. Although most imaging studies have a limited ability to diagnose melanoma, a variety of traditional or advanced imaging techniques are employed, in an attempt to detect occult metastases.

1.1.1. X – Rays

X – rays, the most classical imaging study, is a quick, inexpensive, and easy to perform technique, and can be applied in melanoma staging, especially since the lung is one of the most common metastatic sites. However, only a few lesions produce an appearance that can be correlated to a specific diagnosis. Investigating the use of chest X – ray in patients with localized melanoma, Terhune et al., [4] found that only 0.1% of the patients staged by this method were found to have occult metastatic lesions. In a more recent study, Hofmann et al., [5] reported that chest X - ray showed a yield of 0.2% and a false positive rate of 4.4%.

Still, a chest X – ray in a symptomatic patient remains of some use, and will also be useful as a routine preoperative screening exam.

1.1.2. Ultrasound

In melanoma, ultrasound has been used for both the diagnosis of skin lesions, and staging of regional nodes and abdominal organs. The ability of ultrasound to distinguish between basal cell papilloma and malignant melanoma has been investigated, and ultrasound has been reported to have sensitivity of up to 100%, but with low specificity rates [6, 7]. The addition of color Doppler in the investigation might also further improve accuracy [8].

Ultrasound has also been widely used in the evaluation of lymph node basins in melanoma staging. Compared to clinical examination, ultrasound has shown superior sensitivity rates, with comparable specificity, despite the fact that it is an operator – dependent technique [9-11]. However, in the era of the Sentinel Lymph Node Biopsy technique for lymph node staging of melanoma, ultrasound has limited utility, as its false negative rates remain high, especially in case of small metastatic deposits (2-4mm), and SLNB remains the golden standard for lymph node staging in clinically node – negative patients [12]. Finally, in distant metastases staging, ultrasound is not routinely used, but may be useful in the differential diagnosis of e.g. suspicious liver lesions.

1.1.3. Computed Tomography

Computed Tomography is the preferred imaging technique for the evaluation of abdominal metastases in melanoma patients. Liver metastases from melanoma are typically hypervascular lesions, and therefore the correct phase post contrast infusion is needed to be acquired. On the other hand, chest CT is also superior to chest radiography, more sensitive in detecting subcentimeter lesions and more capable to distinguish solitary from multiple pulmonary lesions [13]. In patients with normal chest radiography, the possibility of discovering additional metastasis in chest CT raises up to 19% in high – risk patients [14]. However, when the CT results in indeterminate findings, patients should undergo further imaging or diagnostic surgery.

1.1.4. Magnetic Resonance Imaging

Magnetic Resonance Imaging (MRI) is an excellent technique to delineate soft tissues, due to its high contrast resolution and multiplanar images.

Table 1. Expected survival of patients with melanoma

Stage	5 – year survival (%)
I	91 – 95
IIA	80
IIB	65
IIC	45
IIIA	65 – 70
IIIB	45 – 55
IIIC	25 – 30
IV	5 - 20

However, it still carries a lot of limitations, due to its high – cost, long examination times, and its patient – related contraindications (claustrophobia, pacemakers, certain surgical clips or metal prosthetic devices).

In melanoma patients, T1 – weighed images give a high signal density for melanoma deposits, consistent with the paramagnetic effect of melanin.

As a result of its increased soft – tissue contrast, MRI is more sensitive than CT in the detection of metastases that involve the brain, liver and musculoskeletal system [15], and results in alteration in the treatment plan in nearly one quarter of the patients. Still, MRI would not be a first – line investigation for staging of melanoma, and it is most useful as an adjunctive method of investigating indeterminate lesions found in previous imaging studies.

1.1.5. Sentinel Lymph Node Biopsy – Nuclear Medicine Imaging Modalities

The reference standard for the lymph node staging in melanoma patients with no clinical evidence of regional nodal metastasis, is sentinel lymph node biopsy (SLNB), a technique that was developed by Morton more than 20 years ago [16], typically performed following intraoperative lymphatic mapping. Formal regional lymphadenectomy is now reserved for patients with clinical suspicion of metastatic adenopathy, which is usually confirmed with ultrasound – guided fine needle aspiration (FNA).

In the event of a negative SLNB, patients are considered to have a clinical stage I/II disease, whereas patients with positive SLNB following a complete regional lymphadenectomy, will require further imaging in order to detect clinically occult metastases. Nuclear medicine imaging modalities, such as positron emission tomography (PET), with or without combination with computed tomography (PET/CT) are also becoming increasingly popular in the staging of melanoma. Their scientific basis lies on the fact that malignant cells have a higher metabolic rate, and this is detected by infusion of a radio-labeled glucose analogue, 18-fluoro-deoxy-D-glucose (18-FDG), which is taken up by tumor cells. However, a PET scan alone offers a limited spatial resolution, and small (< 1cm) or non-metabolically active lesions may be missed. Thus, PET alone is considered to be more accurate in stage III disease rather than stage I/II [17], while SLNB has been shown to have superior sensitivity in stage I/II melanoma patients (Table 2).

The addition of PET images to CT images acquired simultaneously has been the new revolution in Nuclear Medicine Imaging, and offers more accurate localization of 18-FDG uptake. The accuracy of PET/CT is increased compared to PET alone, even in patients with early stage melanoma [18, 19]. PET/CT has the potential of covering the whole body, which is not easy to accomplish with other imaging techniques, as well as an increased spatial resolution compared to PET alone (6mm vs 10mm).

Table 2. Selected studies comparing nodal status detection by SLNB and PET in Stage I/II melanoma patients

Author	No of patients	PET positive (%)	SLNB positive (%)
Wagner et al., 1999	70	3	16.7
Hafner et al., 2000	100	2	26
Wagner et al., 2005	144	9	43

However, some limitations still exist: its specificity is still low, as lesions with increased metabolic rate such as inflammatory or infectious can be falsely considered positive, and there are a small proportion of low – metabolic rate lesions that PET/CT will not detect.

Finally, its increased cost and limited availability pose another drawback to this technique, and its use is mostly reserved for patients with high risk of recurrence after successful resection or response to systemic treatment.

1.2. Assessment of Skin Burns

Burn wounds are a common clinical entity a plastic surgeon has to face in everyday clinical practice. Since burn wounds that heal within a short time (e.g. 2-3 weeks) have an acceptable aesthetic and functional outcome, it is critical that the burn depth is assessed accurately early, in order to better stratify patients that are deemed to undergo surgery that involves excision and grafting, in order to achieve healing within this 2-3 week timeframe.

The initial clinical assessment is usually effective when it comes to burns that are classified as superficial or full thickness, however, in partial thickness skin burns the depth is not well defined and the clinical estimation of the depth is often inaccurate. Studies have shown that in the case of an indeterminate depth burn, the clinical assessment has an accuracy ranging between 65-70%, even when the burn depth is assessed by experienced plastic surgeons [20, 21]. For this reason, much research has focused on potential imaging adjuncts that will assist the clinician in making a correct burn depth assessment.

The foremost among these techniques, that has met great approval among plastic surgeons, was the laser Doppler technique [22]. The laser Doppler technique utilizes the Doppler Effect in order to assess burn depth, as laser light is directed at the moving blood cells in the sampled tissue, and the frequency change of the waves of laser light is proportional to the amount of perfusion in the tissue.

The correlation between burn depth and perfusion has been documented since as early as 1984, when Micheels and colleagues showed that superficial or partial – thickness burns result in supranormal dermal perfusion, whereas deep or full – thickness burns display significantly reduced dermal blood flow [23, 24].

The current evidence in the evaluation of skin burns with laser Doppler is growing [22], and recent studies show that a new technique, the Laser Doppler Imaging is more efficient than LD flowmetry, superseding the latter one. The LDI is usually applied within 48 – 72 hours, and provides a significant aid to the clinical evaluation, predicting the possibility of healing within 21 days, and this has been validated in both adult and pediatric patients. Current limitations of the technique include its increased cost, the topographical artifacts when curved areas of the body are assessed, its difficulty in the assessment of tattooed areas of the body and possible ambiguous results in patients with concurrent infections, peripheral vascular disease or anemia.

Furthermore, there is no current consensus on the cut – off points of perfusion values, and burn centers still have to evaluate their devices independently and find the most suitable cut - off points and levels of burn wound depth stratification. However, the objective benefit of LDI, when used as an adjunct to clinical assessment, has now been well documented, and its use improves the prediction of burn healing and reduces ensures a timely decision to operate.

1.3. Scar Evaluation Using Modern Imaging

Skin scars are the end result of a cutaneous injury, iatrogenic or not, following a series of events that are involved in the wound healing process [25]. Cutaneous scarring is affected by a plethora of genetic, physiologic, environmental and biochemical factors, and all these produce a continuum of scar types (keloid, hypertrophic, atrophic, contracted, fine line, etc.), with up to 70% of the scars being symptomatic, aesthetically unsatisfactory, physiologically distressing or functionally restrictive to the individual [26].

The accurate assessment of the scar allows for better quantification of the scar inflammatory state, its morphology and evolution, as well as its response to interventional or conservative treatments [26]. In the quest of objective adjuncts in scar evaluation, a number of imaging techniques have been evaluated, such as laser Doppler and ultrasonography, along with a bunch of, mostly experimental, other techniques.

Laser Doppler Flowmetry is based on the fact that the blood perfusion in the cutaneous tissue correlates with the extent of the vascularization. Laser Doppler has been extensively used in burn assessment, and when applied to scars, it can act as a predictor during scar maturation, as hypertrophic scars tend to have increased blood flow [27]. The increased cost and low availability is currently the method's main drawback, but as this technology further disseminates, the cost is expected to decrease, increasing its clinical use.

Ultrasound is also a useful method in the assessment of cutaneous problems, and many devices have been used for scar depth quantification [28-30]. Ultrasound has been shown to be able to discriminate between hypertrophic scar and normal scar with good sensitivity and specificity, both in burn and surgical scars.

2. IMAGE – BASED PREOPERATIVE PLANNING IN PLASTIC AND RECONSTRUCTIVE SURGERY

Since the evolution and access to sophisticated imaging techniques has increased in the past decades, plastic surgery is one of the fields that has benefited most.

The detailed information that is acquired by modern imaging techniques allows plastic surgeons to have precise preoperative data related to the actual clinical status of the patient, allowing them to plan flaps in a refined and precise way, selecting the best option for the patient. In the current era of anatomically predefined flaps, preoperative imaging is now a routine method, not only to study the donor and recipient area, but also to improve the surgical outcome and ensure minimal morbidity.

Almost all kinds of available imaging modalities have been used in the preoperative evaluation of vessels in microvascular plastic surgery. These include Doppler ultrasound, angiography, computed tomographic angiography (CTA) and magnetic resonance imaging angiography (MRA) (Table 3). Although the latter two methods are nowadays being increasingly used, there is no consensus on which imaging modality should be used, and, as research in this field is ongoing, this chapter will focus on the use of CTA and MRA in preoperative planning of plastic surgery operations. CTA uses computer – analyzed x-ray images in combination with the infusion of a contrast agent, in order to produce highly accurate reconstruction images of the vasculature [31].

Table 3. Overview of pros and cons of imaging modalities in the preoperative evaluation of the vascular anatomy

Method	US Doppler	CTA	MRA
Pros	Low cost	High sensitivity and specificity	High sensitivity and specificity
	Easily accessible	Higher perforator detection rate	No exposure to ionizing radiation
	Simple use	Currently the gold standard	Better depiction of intramuscular vessels
	No contraindications		
Cons	Operator dependent	Exposure to ionizing radiation	Contraindications (severe obesity, metal or cochlear implants)
	Variable sensitivity and specificity	Medium – to –high cost	High cost
	May be time consuming	Contrast – related risks	Risk of nephrogenic systemic fibrosis
			Inferior to CTA (using 1.5T magnetic field)

CTA: Computed Tomographic Angiography, MRA: Magnetic Resonance Imaging Angiography.

CTA produces more accurate images than Doppler or color Doppler, providing detailed information regarding the intramuscular course of perforating vessels, and may give additional information on incidental findings or anatomic variations [32, 33], and has been used in the preoperative evaluation of both free and perforator flaps.

There is a plethora of studies that have demonstrated the effectiveness of CTA in accurately assessing perforating vessels, most of them in planning Deep Inferior Epigastric Perforator (DIEP) flaps [34-39].

While CTA is often criticized for the high radiation exposure, the benefits of its preoperative use include shortened dissection and operative times, reduced complication rates and, eventually, reduced overall cost. CTA can effectively depict perforators greater than 1mm in caliber and, in several international centers is considered as the gold standard in preoperative imaging of DIEP flaps.

On the other hand, Magnetic Resonance Imaging has also evolved from an initial use for solid organ study to an effective and feasible technique for vascular study.

Even small caliber vessels, including perforator vessels, can now be evaluated with MRA, without the need of exposure to radiation, maintaining high sensitivity and specificity in the evaluation of vessel course and size. Most studies available in the current literature report a sensitivity of 97-100% in the identification of perforators of the DIEA, which is similar to that of CTA [40-42].

However, in the study by Rozen et al., MRA is reported to have a lower perforator detection rate compared to CTA, particularly in perforators < 1mm [41]. These results are likely to be due to the fact that CTA has a better contrast in depicting the vessel course within fatty tissue, whereas, on the other hand, MRA can better depict the intramuscular vessel course.

Finally, a recent study by Hartung et al., suggests that the sensitivity of MRA can be improved when 3.0T magnetic fields are used, compared to 1.5T, offering increased spatial resolution, decreased acquisition time and better visibility of the vessels [42].

Chapter 93

WRIST FRACTURES IN ADULTS: WHAT SHOULD A MEDICAL STUDENT KNOW?

Fares E. Sayegh*, MD, PhD

Aristotle University of Thessaloniki, Thessaloniki, Greece

ABSTRACT

Wrist fractures are common fractures and are seen frequently in the emergency department. They mainly occur in the elderly as a result of a fall on an outstretched hand. Wrist fractures are also seen in high-energy mechanism injuries such as road traffic accidents or a fall from a height. Those fractures are always accompanied with other injuries. The ability to detect the different types of wrist fractures requires an adequate understanding of the anatomy of the wrist, the mechanism that causes that type of injury, and the accurate interpretation of different imaging processes of the bony and articular structures of the wrist. Therefore, appropriate evaluation of the radiological x-rays is important for therapeutic intervention, surgical or conservative, and for the complete restoration of normal wrist function after an injury.

BONY ANATOMY

The wrist is composed of the distal parts of the radius, the ulna, the proximal and distal carpal rows, and the bases of five metacarpals. The distal extraarticular part of the radius is broadened 2-3 cm proximal to the radio-carpal joint and this small area of metaphyseal widening is characterized by a decrease of the amount of cortical bone and increase in the amount of cancellous bone that is weaker and easily predisposed to fracture if an injury of the wrist occurs [5, 6, 7]. On the lateral surface of the distal radius, one can also palpate the radial styloid, a strong cone shaped cortical projection. The Lister tubercle is a bony prominence that is found over the dorsal aspect of the distal radius.

* Corresponding Author's Email: fsayegh@auth.gr.

The intra-articular surface of the distal radius has a fossa for the scaphoid carpal bone where it sits, it is named scaphoid facet or fossa, and another fossa where the lunate carpal bone sits and it is named lunate facet or fossa [5, 6]. A narrow, concave, smooth depression is also found on the medial side of the distal radius. This is called the sigmoid notch and it acts as a seat for the distal ulna. The sigmoid notch facilitates the rotation and provide relative stability to the distal radio-ulnar joint [6] (Figure 1). The carpal bones of the wrist are eight in number and lie in two rows. From the radial to ulnar side, the proximal row consists of the scaphoid (navicular), lunate, triquetrum, and the pisiform carpal bones. Similarly, the distal row, from radial to ulnar, includes the trapezium, trapezoid, capitate, and hamate carpal bones that normally articulate with the bases of the metacarpals. It is important to remember that the proximal carpal bone row is considered and named as intercalated segment as the forces acting on its proximal and distal articulations determine its position [5, 6, 7] (Figure 2). The collapse of this bony anatomy after a wrist injury is an indication of wrist instability. The surfaces of the distal and proximal rows carpal bones are joined together with intrinsic ligaments. As a result, the wrist is separated into different articular compartments; the radiocarpal compartment, the midcarpal, the pisiform-triquetal, the common carpometacarpal, intermetacarpal and the distal radioulnar compartments [6, 7].

IMAGING EVALUATION

In cases where a patient with a wrist injury is presented to the emergency room, a series of radiological views are to be requested. As a start, the standard x-rays; the postero-anterior (PA), and the lateral x-ray should be included. In many cases the detailed clinical examination of the injured wrist may require more radiological imaging in order to better describe the fracture. The therapeutic doctor should recognize (Figure 3, 4):

- 1) The location of the fracture. Is the fracture extra or intraarticular?
- 2) The configuration of the fracture. Is the fracture transverse, oblique, or comminuted?
- 3) The displacement. Is there a change in the radial tilt, length and angle
- 4) Are there any signs of joint instability? (radiocarpal, radioulnar, intercalated)
- 5) Is there any suspicious for an unrecognized underlying fracture of carpal bones? (scaphoid, hamate, triquetrum, ...)

Postero-Anterior Wrist View

This is a standard view of the wrist and one can distinguish the many normal interosseous relationships [5, 6, 7].

In this poster-anterior view one should appreciate;

- 1) The three smooth arcs of the wrist
- 2) The scapholunate joint space
- 3) The ulnar length
- 4) The carpal height

1. Arcs of the Wrists

Three carpal arcs are distinguished along the radiocarpal and midcarpal joints. A line that follows the proximal articular surfaces of the scaphoid, lunate and the triquetrum carpal bones forms arc 1. A line drawn over the distal articular surfaces of the same carpal bones forms arc 2. The arc 3 is formed from a line that follows the proximal articular surfaces of the capitate and hamate carpal bones. In a normal x-ray of a wrist, the 3 carpal arcs are not disrupted and shown to be almost equal in size, smooth, and parallel to each other (Figure 5).

It is important to note that the interosseous carpal and intercarpal spaces are nearly equal in size. However, normal variants of step-off carpal arcs are described.

2. Scapholunate Joint Space

The normal size of scapholunate joint space does not differ from the size of the other joint spaces that lie between pairs of the other carpal bones.

There is a kind of parallelism between the carpal joint spaces. Normally the width of the intercarpal joint space at its midportion measures 2 mm or less and its width does not alter with the wrist in either radial or ulnar deviation.

3. Ulnar Variance (Known as Hulten Variance)

This refers to the change in the length of the ulna relative to the length of radius. This change in length can be found by drawing a line on the distal articular surface of the radius toward the ulna, and another line on the distal articular surface of the ulna. The distance measured between those 2 drawn lines is named the ulnar variance.

Normally both ulnar and radial articular surfaces are at the same level. If the ulna projects more distally than the radius the ulnar variance is considered to be positive. If the ulna projects more proximally, then the ulnar variance is negative.

4. Radial Inclination

It represents the angle formed between a line that connects the radial tip to the ulnar aspect of the distal radius and a second line drawn perpendicular to the long axis of the radius. This angle of radial inclination ranges from 13-30° (Figure 6).

5. Radial Length or Height

It can be measured along the longitudinal axis of the radius, and it is the distance between a line that passes through the distal tip of the radial styloid and a second line passing through the distal articular surface of the ulna. Normally, the radial length measures 11-13mm (Figure 7).

6. Carpal Height

This is a radiological concept that helps in the quantification of the carpal collapse in a patient over time. The height can be found by measuring the distance between the base of the 3rd metacarpal and the distal articular surface of the radius (Figure 8).

Lateral Wrist View

A true lateral x-ray of the wrist is considered when there is parallelism of the long axis of the 3rd metacarpal with the long axis of the radius, and the pisiform carpal bone overlies the distal pole of the scaphoid carpal bone [5, 6, 7].

1. The Longitudinal Axes of Radius, Lunate, Capitate

On a lateral x-ray of the wrist the longitudinal axes through the 3rd metacarpal, the capitate, the lunate, and the radius all fall on the same line.

2. The Capitollunate Angle

It is where the axes of the radius, lunate, and capitate should superimpose with 0-30° angle.

3. The Scapholunate Angle

It is the angle formed between the longitudinal axis of the scaphoid and the long axis of the radius, lunate, and the capitate carpal bones. Normally it ranges between 30-60°.

4. The Palmar or Volar Tilt of Distal Radius

This is the angle that is formed between a line that is drawn tangentially to the most distal articular surface and a perpendicular line to the midshaft of the radius. A normal wrist has a range of 11° of volar or palmar tilt to 4° of dorsal tilt.

Oblique Wrist View

In this view the fractures of the waist of the scaphoid and the tuberosity are better seen [5, 6, 7]. Fractures of the dorsal part of the triquetrum can be also detected.

Moreover, the scaphotrapezial, scaphotrapezoidal, trapezotrapezoidal, capitollunate, and the first carpometacarpal joints are well visualized [5, 6].

Radial and Ulnar Deviation Wrist Views

In both wrist projections, the scaphoid carpal bone is better visualized.

COMMON DISTAL WRIST FRACTURES

Fractures of the distal end of the radius are the most common fracture-injuries seen and treated by orthopaedic surgeons in the emergency room [2]. Looking at the x-ray of such fractures, the therapeutic doctor should be able to interpret and to describe the pattern and the characteristics of such fractures [1, 2, 3, 4]. Therefore, one should understand the location of the fracture; is the fracture line only located in the metaphysis of the radius and does not involve the radial articular surface? (extraarticular fracture).

Does the fracture line extend to the radiocarpal joint? (intraarticular fracture) [1, 2, 5].

It is also important to recognize the configuration of the fracture, is the fracture transverse, oblique, or comminuted? One should recognize if the fracture is unstable, and look for type of displacement of the fracture and if there is any change in the normal radial tilt, length or angle [5, 6].

Moreover, any signs of joint instability and the coexistence of other accompanied fractures of carpal bones or ulnar styloid should be interpreted and described.

1. Colles' Fracture

This is a fracture of the distal end of the wrist. It is one of the most common fractures seen at the emergency department. The incidence of this fracture is increased in the elderly due to osteoporosis. The mechanism of injury is usually a fall on an outstretched hand.

A Colles' fracture is usually a transverse extraarticular fracture, but it could be comminuted and intraarticular. In this fracture, there is impaction and dorsal angulation of the distal fracture fragment (Figure 9).

Therefore beside the recognition of the presence of a transverse metaphyseal fracture of the distal radius, the doctor should look and describe the presence of other fracture features [3, 4, 5, 6]:

1. Extension of the fracture line to the radiocarpal joint
2. Extension of the fracture line medially to the distal radioulnar joint
3. Is there radial shortening due to fracture impaction?
4. Is there a loss of radial inclination?
5. Degree of dorsal angulation in relative to the proximal fracture fragment?

2. Smith Fracture

This is an extraarticular fracture of the metaphysis of the distal radius. It is also called the reverse Colles, as the distal fracture fragment is displaced and angled volarly (palmar direction) relative to the proximal radial fracture fragment. This fracture mainly occurs in younger patients, and the mechanism of injury is a fall on a flexed wrist [2, 4, 5, 6] (Figure 10).

3. Barton Fracture

This is an intraarticular fracture of the distal radial articular surface. The intraarticular fracture fragment is displaced together with the carpus.

This translation or displacement of the distal fracture fragment with the carpus may be in a palmar (volar) or dorsal direction in relation to the shaft of the radius [1, 2] (Figure 11).

4. Hutchinson (Chauffeur) Fracture

This is an oblique intraarticular fracture of the radial styloid. It is rarely displaced and it is better distinguished on a PA view of the wrist [5, 6]. The fracture line may extend to the space between the scaphoid and the lunate fossae causing scapholunate ligamentous injuries that may lead to scapholunate instability or dissociation. The term “chauffeur” fracture was originally described in the early 20th century as an injury that occurred while using the starting automobile crank that suddenly reversed during an engine backfire (Figure 12).

5. Die-Punch Fracture

This is an intraarticular fracture of the distal radius. It is a depressed fracture of the lunate fossa of the articular radial surface as a result of a transverse load transmitted through the lunate carpal bone (Figure 13). Sometimes this type of fracture can be easily missed on a PA wrist view. A good understanding of the carpal arcs of a wrist as seen on a PA wrist view, will help in noticing the disturbance of the smooth carpal arc I that connects the outer proximal convexities of the scaphoid, lunate, triquetrum.

This finding should arouse suspicion of the existence of such a fracture [3, 5, 6].

COMMON CARPAL BONE FRACTURES

1. Scaphoid Fracture

It is the most common fractured carpal bone. It usually occurs in young males after a fall on an outstretched hand while the wrist is extended and radially deviated. If an injury to the scaphoid carpal bone is suspected, a PA, lateral and oblique views of the wrist are the routine x-rays that are required to visualize the scaphoid bone. Views with the wrist in an ulnar deviation (the scaphoid view) will better illustrate the waist of the scaphoid carpal bone [4, 5]. Anatomically, the scaphoid bone has a waist, a proximal and a distal pole. The most common fractures of the scaphoid occur through the waist. Early recognition of the scaphoid fracture is important, as early immobilization of the wrist with a cast is essential for achieving bone union. It should be emphasized that the blood supply of the scaphoid carpal bone is unique as the entire blood supply of this carpal bone enters from its distal pole. Therefore, fractures of the scaphoid and especially of the distal pole may predispose to avascular necrosis [3, 4, 5] (Figure 14 a, b).

2. Triquetrum Fracture

The triquetrum fracture is considered the 2nd most commonly injured carpal bone. The dorsal avulsion fracture of the triquetrum could be easily missed on conventional x-rays of the wrist. In cases where there is a clinical suspicion of such fracture, a CT tomography is the method of choice (Figure 15).

3. Hamate and Hook of the Hamate Fracture

Usually the fracture of the hamate may be detected on a plain x-ray. Fractures that involve the hook of the hamate are difficult to notice on standard views. Beside the use of using a carpal tunnel view, CT, or MRI to detect a clinically suspicion fracture of the hamate or hook of the hamate, a bone scan is another option to locate the fracture site [5, 6, 7] (Figure 16).

4. Pisiform Fracture

This fracture is usually the result of a direct blow to the pisiform carpal bone. Pisiform fractures occur in 1-3% of all the carpal bone fractures and are difficult to detect on standard x-rays. A carpal tunnel view, a lateral oblique, or a radial deviation view is sometimes necessary to show the fracture. MRI, and CT scan may also help in detecting the fracture [6] (Figure 17).

CONCLUSION

Fractures of the distal radius and the carpal bones are common and complex fractures that are seen routinely in the emergency room. This chapter provides the medical students with a concise and complete understanding of some of the common wrist fractures that they should know during their medical studies.

Chapter 94

MINIMALLY INVASIVE MIDFACE LIFT USING ABSORBABLE SUTURES WITH CONES: A STEP BY STEP PROCEDURE

***M. Goisis, A. Di Petrillo, L. Rosset, A. Kunderfranco,
S. Mele, E. Stella and S. Khabouri***

ABSTRACT

Background: Since the invention of the first barbed (short) suture by Sulamanidze in the late 1990s, facial soft tissue lifting with subdermal sutures has a significant attraction for physician and patient alike. This study aimed to describe the authors' experience and the office techniques they have adopted to counteract the descent and laxity of facial soft tissues.

Method: A retrospective chart review was performed during a period of 15 Months, from March 2013 to June 2014. The procedure was performed in 131 patients under local anesthesia using 2-0 absorbable polylactic sutures with 4 polylactic cones in their distal section (Silhouette Lift, Irvine, California).

The face was marked preoperatively to determine the appropriate vector of the thread and its two end exit points. The results were assessed objectively using serial photography with Canfield Camera System and subjectively according to patient assessment. Complications also were recorded.

Result: All but two patients were satisfied with the outcomes after treatment. Consensus ratings by two independent surgeons found that objective outcomes were divided among "excellent," "good," and "fair." The postoperative course was uneventful except for two patients who presented with major hematoma and another patient who had minor skin dimpling. These three complicated cases were resolved spontaneously without any surgical interventions.

Conclusion: The advantages of this technique are its simplicity, the fact that it produces no traumatic effects, and the fact that it can be performed with local anesthetic, reducing surgical time over current approaches.

INTRODUCTION

The process of facial aging involves all the layers of tissues. A general loss of volume is observed in the extracellular matrix of connective tissues, due to reduced synthesis of glycosaminoglycans and hyaluronic acid. Furthermore, alterations in the ultra structure of collagen and elastin lead to reduction of elasticity and increase of sagginess of soft tissues. The hypotrophy typical of the aging face and neck is then a process involving not only the skin but even fatty tissue and muscle.

The intermittent use of resorbable cone or barbed wires is aimed at preventing and treating the tissue sagginess and reinforcing the soft tissue of the face. The suture suspension technique falls in between the more aggressive and invasive procedures (for example, face lift) and the less invasive ones (such as fillers or Botox); the permanency of the results could measure up to 2 years. Coned and barbed wires allows accurate facial tissue repositioning by exerting immediate traction. Furthermore an even stronger force contrasting gravitational pull is provided by new collagen fibers formation. Starting around 2 months after the placement of the wires, the process of wire resorption leads to synthesis of collagen all around the wire, enhancing the traction over the tissues. The initial traction is produced by the presence of the slow-absorbing cones or barbs, which are reinforced by the buildup of new collagen formation. After the cones or barbs are reabsorbed the tissue traction is maintained by the collagen around and inside a series of knots interpolated along the wires. Further applications of wires on the same area are possible to enhance the support over soft tissue.

METHODS

A retrospective chart review was performed during a period of 15 Months, from March 2013 to June 2014. The procedure was performed in 131 patients under local anesthesia using 2-0 absorbable polylactic sutures with 4 polylactic cones in their distal section (Silhouette Lift, Irvine, California).

61 patients underwent coned wires lift on the cheeks for correction of medium and low facial sagginess; 12 patients underwent wire lift in the eyebrow and frontal region; 29 patients underwent lift of the cervical region; 29 patients underwent coned wires lift in both the facial and cervical area

The face was marked preoperatively to determine the appropriate vector of the thread and its two end exit points. The results were assessed objectively using serial photography with Canfield Camera System and subjectively according to patient assessment. Complications also were recorded.

The patients have been asked to give us an anonymous written feedback regarding the short term results with a simple scale by choosing among: very good, good, fair, bad, very bad.

For each patient pre and postoperative photos were sent to two independent surgeons to evaluate the aesthetic outcome. Results could be rated by a single scale marking among: very good, good, bad, very bad.

RESULTS

All but two patients were satisfied with the outcomes after treatment. Subjective marks provided by patients ranked among “very good” (51 cases), “good” (73 cases), “fair” (5 cases), “bad” (2 cases). Consensus ratings by two independent surgeons found that objective outcomes were divided among “excellent” (in 53 cases), “good” (in 49 cases), and “fair” (in 29 cases). The postoperative course was uneventful except for three patients. Among these, 2

patients presented with major hematoma and another patient had minor skin dimpling. The two cases with hematoma resolved spontaneously without any surgical interventions. The patient presenting the skin rippling needed surgical intervention to remove the wire.

CONCLUSION

The coned wire lift offers several advantages over classical approaches like surgical facial lifting.

Because of its simplicity it can be executed under simple local anesthesia. Surgical time is dramatically reduced, with great advantage for the surgeon and for the patient. The absence of skin incisions leads to immediate recovery and absence of visible scars.

This technique can be associated with filler or botulin toxin injections in the same surgical time, to optimize the aesthetic enhancement and reduce patient stress.

Chapter 95

FREE FLAP BREAST RECONSTRUCTION: NEW UPDATES AND REFINEMENTS ON A WELL ESTABLISHED TECHNIQUE

Cedric L. Hunter, MD and Gordon K. Lee*, MD

Division of Plastic Surgery, Stanford University Medical Center,
Palo Alto, CA, US

ABSTRACT

The abdominal flap is the most common method of autologous breast reconstruction worldwide. Advocates argue the predictability and ability to create a more natural breast mound exceed that of implant based reconstruction. The transverse rectus abdominis (TRAM) flap has evolved from a pedicle flap to a free myocutaneous flap, and now to a deep inferior epigastric perforator (DIEP) flap as microsurgery technique and skill has improved. Multiple recipient vessels have been used historically including the thoracodorsal, lateral thoracic, thoracoacromial, transverse cervical, and internal mammary vessels. The internal mammary artery (IMA) and vein (IMV) are common recipient vessels in today's practice as the dissection can be done quickly and their medial position allows for medial placement of the reconstructed breast mound. During the oncologic portion of the case the axillary lymph nodes are often sampled with either sentinel lymph node biopsy or variations of axillary lymph node dissections. While the axilla is a major nodal basin for breast tissue drainage some studies report as much as 20% drainage to the internal mammary lymph node basin. The dissection of the internal mammary vessels also affords an opportunity to sample internal mammary lymph nodes that may significantly alter cancer staging and treatment. Traditionally the anastomosis from the free flap to the IMA and IMV is performed in an antegrade manner with a single artery and vein. However, when additional inflow or outflow is needed an additional anastomosis can be performed in the same zone with retrograde anastomosis to the IMA and IMV with success. While the free TRAM is currently the gold standard in autologous breast reconstruction, pre-existing abdominal scars are often a deterrent to the reconstructive surgeon given concern for potential ischemic complications. Techniques

involving flap design modification and supercharging or turbocharging the flaps with additional anastomoses from contralateral deep inferior epigastric vessels or superficial inferior epigastric vessels provides the reconstructive surgeon with tools for successfully managing potential problems associated with abdominal scars.

Often clinical analysis of bleeding flap edges is sufficient for assessing flap viability intraoperatively; however, new imaging modalities involving intraoperative laser-assisted indocyanine green (ICG) angiography are also being used as an adjunct to assess tissue perfusion. Other vascular imaging studies such as computed tomography angiography (CTA) are increasingly being used preoperatively to assist with perforator identification and free flap planning. The techniques discussed within this chapter highlight recent advances in perforator based microsurgery, the reconstructive surgeon's potential contribution to breast cancer staging, strategies for managing abdominal scars in abdominal based free tissue breast reconstruction, and the use of vascular imaging for the reconstructive surgeon. These techniques and tips help the reconstructive surgeon to provide excellent and predictable results while limiting complications.

INTRODUCTION

Since the birth of breast reconstruction, the reconstructive plastic surgeon has focused on developing a reliable procedure and improving aesthetic results while limiting complications and donor site morbidity. In 1982, Hartrampf brought the transverse rectus abdominis musculocutaneous (TRAM) flap to the forefront of autologous tissue breast reconstruction following mastectomy.

This technique allowed the reconstructive surgeon to utilize a transverse island of abdominal skin, subcutaneous tissue, and its underlying musculature based upon the superior epigastric vessels to recreate a natural breast mound without the need for an implant [1].

While this was an improvement to previous techniques and allowed a single stage reconstruction, there was abdominal wall morbidity due to the sacrifice of the rectus abdominis muscle. The continued evolution of technology and skill provided substantial advances that have pushed the field of breast reconstruction towards the increased utilization of free flap techniques capable of sparing abdominal muscles. The realization that the dominant blood supply to the rectus abdominis musculature and overlying abdominal wall was through the deep inferior epigastric artery and the added benefit of preserving the medial and inferior inframammary fold by avoiding tunneling of the pedicled flap also encouraged use of the free TRAM flap [2].

Current microsurgery training involves both live in operating room training in an apprenticeship model and self-directed education through interactive alternative modalities such as practice models and web-based curricula. While microsurgery training is incredibly diverse the development of reliable tools for assessing microsurgeon development is key.

One such scale for evaluating microsurgeons in training is the Stanford Microsurgery and Resident Training (SMaRT) scale, which has been validated previously [3-6]. As microsurgery techniques and training improve, the field continues to strive for improving aesthetic results and limiting donor site morbidity, which has led to the transition from the primary utilization of the free TRAM flap to utilization of the free muscle-sparing TRAM flap, the deep inferior epigastric artery perforator (DIEP) flap, and the superficial inferior epigastric artery (SIEA) flap (Figure 1 and Figure 2).

Each of these flaps utilize the same lower abdominal skin and fat as a donor site but with varying degrees of abdominal wall donor site morbidity based upon the extent of muscle that is used. Despite the varying degree of abdominal wall violation these abdominal flaps are tolerated well by the patient and in some cases have been shown to have a lower incidence of complications when compared to implant based breast reconstructions [7].

In today's practice, for autologous breast reconstruction lower abdominal tissue remains a preferred option by most reconstructive surgeons and perforator flap transfer is quickly becoming the gold standard [8]. In addition alternative non-abdominal tissue flaps including the superior gluteal artery perforator (SGAP) flap, the latissimus dorsi flap, and the transverse gracilis myocutaneous (TUG) flap all help to provide the reconstructive surgeon with a large toolbox of options for creating an aesthetic breast with autologous tissue when lower abdominal tissue is unavailable or not preferred by the patient.

RECIPIENT VESSELS

Historically, a variety of blood vessels have been used as potential recipient vessels for microvascular anastomosis in free flap breast reconstruction. Recipient arteries have included internal mammary, thoracodorsal, thoracoacromial, posterior humeral circumflex, circumflex scapular, and the axillary artery. Recipient veins have included internal mammary, thoracodorsal, cephalic vein of the arm, axillary vein branches, thoracoacromial vein, scapular circumflex, and the axillary vein [9]. While the use of the axillary, scapular

circumflex, and thoracoacromial vessels are infrequent; they can serve as lifeboats in the event of damage and unavailability of the primary planned vessels. The thoracoacromial vessels supply the pectoralis major muscle and can be found below the clavicle in the midclavicular region on the undersurface of the pectoralis major muscle. The circumflex scapular vessels are found where they join the thoracodorsal vessels to form the subscapular system. Tracing the subscapular system in a retrograde fashion into the axilla identifies the axillary vessels. Care must be taken to avoid traction injury to the brachial plexus during this dissection. Currently, the two most common recipient vessel sites for free tissue breast reconstruction are the thoracodorsal and internal mammary vessels.

In the case of immediate breast reconstruction following modified radical mastectomy in which axillary lymph node sampling is performed, the thoracodorsal vessels are either fully or partially exposed by the oncologic resection requiring minimal preparation by the reconstructive surgeon. Ideally, the reconstructed breast mound position should be medial enough to create medial fullness and cleavage for improved aesthetics. This is often difficult to achieve with anastomosis to the thoracodorsal vessels given their lateral location in the axilla. For improved results the thoracodorsal vessels must be dissected free not only from the surrounding tissue, but also freed from the branches to the serratus muscle to the level of the scapular circumflex vessels for sufficient length. In addition, for successful mound placement with use of the thoracodorsal vessels a long donor pedicle is needed.

Today, many surgeons prefer to use the internal mammary vessels as recipient vessels for breast reconstruction. This mirrors a change in the increased use of sentinel lymph node biopsy over axillary lymph node dissection for clinically uninvolved axillary lymph nodes. There are notable benefits to using the internal mammary vessels as primary recipients. In delayed reconstruction fresh tissue planes with lack of perivascular scarring from previous operations decreases the risk of damaging the recipient vessels during exposure. In delayed or immediate reconstruction the more medial position of the flap improves aesthetics and provides better positioning for vessel anastomosis [10, 11]. In cases of delayed axillary dissection after sentinel lymph node biopsy an internal mammary anastomosis circumvents possible damage to the pedicle, which would be at significant risk had the thoracodorsal vessels been used. Furthermore internal mammary vessel use as recipient vessels broadens the reconstructive surgeons flap options, as a shorter pedicle length can be accommodated and still allow medial placement of the flap while limiting lateral fullness [12].

The senior author prefers to use the internal mammary vessels as first-line recipient vessels for breast reconstruction when available (Figure 3). The internal mammary vessels are approached by elevating a flap of pectoralis major muscle overlying the third rib exposing the underlying rib and intercostal muscles. The perichondrium of the third rib is then incised along the anterior surface of the costal cartilage from the sternal junction to the costochondral junction. Blunt and sharp dissection is used to separate the perichondrium from the underlying cartilage on the anterior and posterior surface. The cartilage is then removed with a rongeur. The deep perichondrium is then incised and reflected from lateral to medial. Bipolar electrocautery and hemoclips are used to control small branches from the internal mammary vessels. Care must be taken to avoid injury to the underlying pleura and lung during the dissection. Once the internal mammary vessels are identified the exposure is increased by dividing the intercostal musculature from the second to the fourth rib. The internal mammary vein tends to be larger on the right side compared to the left. It is important to select the appropriate costal cartilage for removal as the internal mammary veins decrease

in size and bifurcate at or below the fourth interspace making venous anastomosis more difficult below this level [10]. After adequate exposure the vessels are generally divided at the level of the fourth rib for sufficient length during microscopic anastomosis (Figure 4). While the use of the internal mammary vessels in free flap breast reconstruction is becoming more widespread, it is not without its drawbacks. One particular drawback is that after the internal mammary vessels are used for breast reconstruction, they are no longer available for use as an arterial conduit in coronary revascularization. Studies have noted that the incidence of cardiovascular disease in women with breast cancer who have undergone free flap breast reconstruction is quite low as women with pre-existing coronary artery disease or significant comorbidities are likely to undergo a more simple operation such as implant based reconstruction.

Figure 3. Exposed internal mammary artery and vein.

Figure 4. Free flap anastomosis to internal mammary artery and vein.

Additionally the increasing use of percutaneous angioplasty procedures decreases the need for mammary bridge in coronary revascularization. Overall, the use of internal mammary vessel use in breast reconstruction surgery is quite safe; however, this potential drawback should be discussed with the patient [13].

VASCULAR OPTIMIZATION

Venous Outflow

After vessel anastomosis and flap inset, one major complication that can be seen with free flap breast reconstruction is venous congestion. DIEP flap venous congestion is multifactorial and is influenced by patient factors (i.e., smoking history, obesity, etc.), technical expertise, and anatomy of the venous system. The reconstructive surgeon must be cognizant and capable of managing potential venous outflow complications that could comprise the reconstructed breast. In the past there were reports of managing venous congestion with cephalic vein harvest and transfer to augment venous drainage and reduce necrosis as either primary venous drainage or additional venous drainage [14]. Significant advances in the understanding of the venous drainage system of the lower abdominal tissues as well as the internal mammary vascular system has allowed for improved methods of augmenting and managing venous drainage after flap transfer.

Anatomic studies of abdominal based tissue flaps have noted that the superficial inferior epigastric vein (SIEV) or deep inferior epigastric vein (DIEV) alone may not be fully capable of supporting drainage of the entire flap leading to venous congestion if not appropriately addressed. If congestion is appreciated intra-operatively this is addressed with 1) separate anastomoses of the DIEV and the SIEV, or 2) if truly one system is dominant (superficial vs. deep) then single anastomosis of the dominant system with or without vein graft is justified. The senior author has reported harvesting the DIEV as a vein graft in cases of SIEV dominance when additional vein length is needed [15]. When needed there are several sources of additional drainage include the external jugular vein, external facial vein, thoracodorsal vein, etc. [14, 16, 17]. When performing primary anastomosis to the internal mammary vessels, one often appreciates that the internal mammary vein has already branched at the level of the anastomosis. In this case, the venous flow can be augmented by utilizing this paired system and performing additional venous anastomosis with SIEV or contralateral DIEV to this second internal mammary vein. In the absence of a branched or paired internal mammary vein another attractive option is to join the superficial and deep drainage systems by performing an additional anastomosis between the DIEV and the SIEV for venous augmentation. Yet another option, and that preferred by the senior author, in the absence of paired internal mammary veins is to perform independent antegrade and retrograde anastomosis to the internal mammary vein after division. We have experienced successful results with utilization of the distal internal mammary vein stump at our institution and there are a few series that have also reported positive results with this technique [18, 19]. Previous studies have noted or assumed that the lack of valves in the internal mammary veins contribute to the success of internal mammary vein use as a conduit in either an antegrade or retrograde fashion [20, 21]. On the contrary, Mackey et al. performed an anatomic study of the internal mammary veins and noted that 43% of cadavers had valves in at least one vein or major branch. They suggested that given the reported success it was likely that bulk of retrograde flow in the IMV occurs through collaterals and communicating side branches, or valve incompetence allowing regurgitant flow [22]. Options for antegrade and retrograde anastomosis include: 1) In the case of DIEP vena comitans, the larger can be anastomosed to the proximal limb in an antegrade fashion and the smaller can be anastomosed to the distal

limb in an retrograde fashion; 2) the deep inferior epigastric vein can be anastomosed to the proximal limb and the SIEV can be anastomosed to the distal limb in a retrograde fashion; and 3) for bipediced DIEP flaps the internal mammary vein can again be used in an antegrade and retrograde fashion. By utilizing the internal mammary vein for retrograde flow, distal vein grafts and morbidity associated with additional dissection can be avoided. The retrograde use of the internal mammary vein provides another avenue for flap salvage, venous supercharging, and double pedicle reconstruction when appropriate. These all highlight the importance of preserving the SIEV on both sides and obtaining maximal length during the initial dissection. When no additional outflow can be established in venous congestion, leech therapy is considered for venous decompression to avoid venous stasis and thrombosis.

Arterial Inflow

While retrograde use of the internal mammary vein provides an additional option for venous drainage, retrograde anastomosis to the internal mammary artery provides the reconstructive surgeon with a means for augmenting vascular inflow to the flap. While the first choice for autogenous tissue breast reconstruction is the single pedicle flap, there are circumstances where similar to the need for increased venous drainage the reconstructive surgeon will be faced with a need for increased arterial in-flow. The increase in arterial inflow often comes in the form of a double pedicle flap. In 1990, Hartrampf et al. described the benefit of the double-pedicle TRAM: 1) in the presence of a midline scar when reconstruction requires greater tissue than that contained in the hemi-abdomen, 2) when the volume of the tissue needed for reconstruction was large and exceeded that which could reliably be carried on a single pedicle, and 3) those at high risk for partial flap necrosis [23]. The use of bilateral rectus muscles for bi-pediced flaps resulted in significant abdominal wall morbidity [24]. Other techniques involving “supercharging” or “turbocharging” were developed to improve blood flow in the uni-pediced flap. In the “supercharged” flap the deep inferior epigastric vessels or the superficial inferior epigastric vessels were anastomosed to independent and unrelated source vessels in the axilla such as the thoracodorsal vessels [25, 26]. Whereas, in the “turbocharged” flap the vascular augmentation was provided by a source vessel already intrinsic to the flap such as anastomosis of the deep inferior epigastric vessels to each other creating a loop [27]. As the use of free flaps increased techniques such as the bipediced free TRAM flap with anastomosis to the thoracodorsal and serratus collateral vessels increased in popularity [28]. As changes in reconstructive surgery technique often mirrors change in technique of the extirpative surgeon, decreased axillary dissection resulted in an increase of internal mammary artery use for recipient vessels and a movement away from combining internal mammary vessels and axillary vessels for bipediced free flaps to the use of internal mammary vessels alone with two sets of microvascular anastomosis to the proximal and distal ends of the transected internal mammary vessels [29, 30]. When vascular augmentation is needed for DIEP flap breast reconstruction the senior author prefers to utilize the proximal and distal cut ends of the internal mammary vessels for anastomoses to the deep inferior epigastric vessels or superficial inferior epigastric vessels in an end-to-end fashion. The retrograde flow through the distal cut end has been observed to provide sufficient flow for needed augmentation.

MANAGEMENT OF ABDOMINAL SCARS

The presence of pre-existing abdominal scars presents a challenge to the reconstructive surgeon as the scars can place the free flap or remaining abdominal wall tissues at risk for necrosis. The presence of an abdominal scar requires the reconstructive surgeon to recognize the potential challenge to tissue perfusion and make necessary modifications to flap design and/or harvest technique to mitigate complications. There are extreme cases where multiple abdominal scars may be a contraindication to surgery; however, abdominal scars in and of themselves are not absolute contraindications to abdominal tissue based autologous breast reconstruction. As mentioned, Hartrampf noted early on that patients with large tissue requirements and a midline abdominal scar benefited from double pedicle TRAM flaps [23]. This technique resulted in considerable abdominal wall weakness after the harvest of bilateral rectus abdominis muscles [31]. Other techniques for vascular augmentation were developed to prevent flap necrosis. Berrino originally described the “Parasite TRAM Flap” which involved harvesting a unilateral superiorly based pedicled TRAM flap and utilizing retrograde flow from the ipsilateral deep inferior epigastric vessels to supply the contralateral deep inferior epigastric vessels [32]. As free flap breast reconstruction became more prevalent others have compensated for the loss of volume by stacking free hemi-DIEP flaps with varying recipient vessels for antegrade and retrograde flow in the presence of a midline abdominal scar [33, 34]. There have been numerous modifications for in-flap vascular augmentation across midline scars that have included anastomosing a premuscular branch off the main deep inferior epigastric artery pedicle across the midline to the proximal end of the contralateral deep inferior epigastric vessels, or creating an anastomosis between the stump of the superior epigastric vessels to contralateral paraumbilical perforators [35-37].

The senior author prefers to use the DIEP flap as a first choice to create an aesthetic breast despite the presence of abdominal scars. With necessary adjustments in flap design and harvest the DIEP flap is safely done in patients with pre-existing abdominal scars. We routinely identify the superficial inferior epigastric vessels intraoperatively and dissect them for a minimum of 4-5 cm through the subcutaneous tissue for added length. These vessels are then preserved for possible later use. A recent anatomic study notes a 94% incidence of the SIEA on CTA; however, only 24% had a diameter > 1.5 mm. The SIEV was present in all cases [38]. The identification and preservation of these vessels when possible affords the reconstructive surgeon added flexibility for managing pre-existing abdominal wall scars. Each case is to be considered based on a number of factors including, the location of the abdominal scar, whether the reconstruction is unilateral or bilateral, and the volume of tissue needed for a symmetric reconstruction.

In the case of a midline infra-umbilical scar, a patient needing a unilateral reconstruction in the presence of a large and pendulous native breast, the reconstruction will require a large amount of tissue often crossing the midline and preventing the use of a hemi-DIEP flap. In this case a bipedicled DIEP flap is harvested to provide perfusion on both sides of the scar.

Other viable options include a DIEP pedicle on one side and an SIEA pedicle on the other side, or a bipedicled SIEA flap if a smaller volume is required (Figure 5). For bilateral reconstructions or small volume unilateral reconstructions the midline scar marks the medial edge of the flap. In cases of a midline supra-umbilical scar, there is no change in flap design; however, the scar can tether the skin to the fascia making donor site closure difficult.

Complete undermining of the skin and subcutaneous tissue flaps to the xiphoid past the scar should eliminate this problem.

The paramedian scar is encountered less frequently, yet can be a cause of significant morbidity if not addressed appropriately. For bilateral and unilateral cases one must ensure that there are perforators on each side of the scar. In unilateral breast reconstruction we preferentially harvest a bipediced DIEP flap and proceed if the scar is medial to the lateral perforators. In bilateral cases or when the scar is located lateral to the deep inferior epigastric perforators we utilize the superficial inferior epigastric vessels to supercharge or turbocharge the flap for blood supply across the scar [39]. In these cases we prefer to perform two independent anastomoses to the proximal and distal cut ends of the internal mammary artery and vein limiting the need for further dissection into the axilla to access the thoracodorsal vessels [34] (Figure 6).

Figure 5. Midline infraumbilical scar. A) Preoperative photograph of a patient with midline infraumbilical scar and left mastectomy defect. B) Intraoperative photograph of harvested abdominal tissue flap. C) Intraoperative photograph of bipediced DIEP flap, pedicles marked with arrows. D) Postoperative photograph of patient with a bipediced DIEP flap for left breast reconstruction and right breast mastopexy for symmetry.

With a pre-existing low transverse or pfannenstiel incision scar the flap is positioned more inferiorly so that the scar becomes the inferior border of the flap. Flap dissection and vessel selection may then usually proceed as planned. In theory the perforators and deep inferior epigastric vessels are preserved as Pfannenstiel's original description describes a transverse skin incision with vertical splitting of the rectus muscles through the linea alba to access the pelvis [40, 41]. Despite this description it is prudent to fully evaluate for intact source vessels prior to completing flap harvest, as it is not uncommon to encounter transected muscle and source vessels or an undermined flap with damage to abdominal wall perforators jeopardizing the ability to safely harvest an abdominal flap. If there is any question of perforator viability the flap should be harvested as either an MS-TRAM or free TRAM flap.

The subcostal scar, often used for open cholecystectomy, if low enough can be incorporated as a superior edge of the flap. When the scar is too high to incorporate into the incision modifications are made to both flap design and harvest. While the deep inferior epigastric vessels are remote from the scar, they play a key role in providing perfusion to the abdominal tissue below the scar as often the rectus muscle and superior epigastric arteries have been transected. Harvest of the deep inferior epigastric artery places the remaining abdominal wall at risk for ischemic complications.

In this case the designed peaks of the abdominal flap are lower than normal and the flap is smaller to preserve a broad base of tissue beneath the scar to perfuse the remaining skin flap. Undermining of the skin and subcutaneous flap near the scar is limited to only that what is needed for tension free closure in an effort to preserve nearby perforators to the skin (Figure 7).

Figure 6. Paramedian scar. A) Preoperative photograph of a patient with a right paramedian scar and bilateral mastectomy defects. B) Postoperative photograph of patient with bilateral DIEP flap breast reconstruction. The left breast is reconstructed with a bipedicle DIEP and SIEA flap to preserve as much volume as possible.

Right lower quadrant or McBurney's incisions for open appendectomy result in abdominal scars that could compromise the lateral edges of the DIEP flap. In these cases if the orientation and location of the scar is amenable, it is best served to shift the flap so that the scar marks the inferolateral edge of the flap. When this is not possible and the scar has to be included to increase flap volume the SIEA and SIEV are available to supercharge or turbocharge the flap and perfuse the area across the scar (Figure 8).

Figure 7. Subcostal scar. A) Preoperative photograph of a patient with a right subcostal scar and right breast cancer. B) Postoperative photograph after patient has undergone bilateral mastectomy and bilateral DIEP flap breast reconstruction with subsequent NAC reconstruction and tattooing for color.

Figure 8. Right lower quadrant scar. A) Preoperative photograph of a patient with a right lower quadrant scar from a McBurney's incision and bilateral mastectomy defects. B) Postoperative photograph after bilateral DIEP flap breast reconstruction. She has yet to undergo NAC reconstruction.

If the SIEA and SIEV are unavailable and there are ischemic concerns beyond the scar excision of the ischemic portion of the flap is recommended. Although there has been no demonstrated increase of flap or donor site complications for DIEP flaps in the presence of abdominal scars from laparoscopic port placement, port scars in the vicinity of the vascular pedicle and perforators can increase the technical difficulty of the dissection [42].

The key when performing autologous breast reconstruction with abdominal tissue in the presence of pre-existing abdominal scars is providing independent perfusion on both sides of the scar.

Tissue perfusion should be assessed intraoperatively for final decision-making and any evidence of venous or arterial insufficiency should prompt vascular supplementation.

IMAGING

There has been a growing popularity for the use of preoperative and intraoperative imaging amongst breast reconstructive surgeons. The most critical aspect of designing and harvesting the DIEP flap is determining the amount of viable tissue that can safely be harvested on a particular perforator. Doppler sonography with or without color duplex imaging has been used to localize cutaneous perforators with high sensitivity allowing preoperative identification. Qualitative assessments based on the harshness of the sound provided a subjective comparison for perforator dominance within a certain skin territory [43, 44]. However, Doppler sonography has its drawbacks including detecting vessels that may be too small to support a given skin flap, inability to identify location of perforator take off, and operator dependence [45]. Due to increased detail and reproducibility, preoperative imaging in the form of computed tomography angiography (CTA) has largely supplanted previously used color duplex sonography in assisting with the planning and selection of perforators for flap harvest. Multidetector-row computed tomography (MDCT) is a recent innovation that allows rapid simultaneous acquisition of multiple thin collimated slices with high spatial resolution and low artifact. The time of acquisition is 10-12 seconds and the total procedure time takes about 10 minutes to perform. The data is then used to reconstruct 1 mm slices and reformatted images in multiple planes (coronal, axial, sagittal, and oblique) as well as a three-dimensional volume reconstruction [46]. Reports suggest that with CTA perforator mapping operative times and postoperative complications associated with partial necrosis of the flap are decreased [47, 48]. In addition to its utility in evaluating free flap donor site anatomy, CTA can also be used to evaluate recipient site anatomy and detect vascular anomalies that can alter the surgical plan, particularly in the cases of traumatic injury reconstructive procedures [49]. While there is acknowledgement that CTA can indeed accurately identify perforators and provide a roadmap for the surgeon there are drawbacks with regard to radiation exposure, need for intravenous contrast media, and increased cost. In a recent study by Mathes et al., they noted that 44% of abdominal perforator flaps involved intraoperative changes due to features not seen on preoperative CT imaging that resulted in the use of additional perforators that were not a part of the initial preoperative plan or the abandonment of initially planned perforators. They noted that while CTA does provide an excellent roadmap for surgical planning and can facilitate flap dissection, it is not a panacea for free flap breast reconstruction. The surgeon must consider not only the anatomical aspects, but

also the functional aspects such as location, intramuscular course, and intervening muscle between perforators [50].

More recently, magnetic resonance angiography (MRA) has shown promise in perforator imaging. High field 3-Tesla MRA is capable of producing detailed, multiplanar images, and three-dimensional reconstruction without the associated radiation exposure seen in CT imaging.

Some have utilized blood-pool contrast agents such as gadofosveset trisodium for contrast-enhanced MRA. Reportedly, gadofosveset trisodium is retained in the intravascular space resulting in higher spatial resolution, in contrast to the conventional gadolinium-based contrast [51]. This technology is in its early stages and still requires further investigation. In general, preoperative imaging when used should not replace or supersede clinical judgment, but can be used as an adjunct for the reconstructive surgeon in preoperative planning. At this time the necessity of and clinical utility of preoperative imaging remains a topic of debate. Currently, we do not routinely obtain preoperative imaging studies.

(A)

(B)

Figure 9. Ischemic complications. A) Flap ischemia of the right reconstructed breast that will require debridement and alternative reconstruction. B) Ischemia of lower breast skin flaps in breast reconstruction.

With regard to intraoperative imaging, there are new imaging modalities such as intraoperative laser-assisted indocyanine green (ICG) angiography that are being used as an adjunct to help assess tissue perfusion. Inadequate tissue perfusion is one of the known key causes to early complications in free flap surgery [52] (Figure 9). To identify areas of decreased perfusion, laser assisted ICG angiography begins with intravenous injection of ICG fluorescent dye, which binds to plasma proteins confining the dye to the intravascular compartment as it travels rapidly through the vascular system. The dye fluoresces at 806 nm. Following stimulation with laser energy the fluorescence pattern can be captured on a charge-coupled device camera or monitor for dynamic and real time images in the operating room [53, 54]. Similarly, fluorescein has been used in the past as a perfusion marker; however, capillary leakage, and prolonged clearance of 12-18 hours limited its utility as a useful intraoperative tool [55, 56]. In contrast, ICG is not as susceptible to capillary leakage and with increased clearance repetitive dye administration may occur after 9 minutes for perfusion re-evaluation [54]. The infrared laser and ICG are capable of demonstrating dermal and superficial soft tissue perfusion to a depth of approximately 3.6 mm [57].

This technology has wide applicability to the plastic surgeon for evaluation of all components of the flap including, skin, fat, fascia, muscle, and nipples in breast reconstruction, and arterial and venous flow in microsurgery [58] (Figure 10).

A major drawback with any form of vascular imaging is that the observed imaging only produces a single snapshot of perfusion at a given time. For ICG angiography in particular, while the surgeon may obtain real-time qualitative data with regards to flap perfusion at time point zero, ICG angiography cannot account for resolved vasospasm or the opening of “choke vessels” at a later time point. Blindly accepting that areas of decreased perfusion on ICG angiography are and will remain ischemic and later necrotic could result in resection of tissue that may have survived with more time. While this modality has been correlated with clinical outcomes and has been used for surgical decision-making, at this time there are no quantitative perfusion thresholds above which tissue survival can be anticipated. Interestingly, in the rat model, skin necrosis has been appreciated when perfusion was less than 25% of reference skin and delayed wound healing was seen in a human study with a signal of less than 60% of normal skin [56, 59]. This technology remains in its initial phases and more basic work is needed in defining the correlation between tissue perfusion and necrosis to develop predictive guidelines and strategies for clinical use. At this time while clinical judgment of the flap based on tissue color, capillary refill, flap temperature, and dermal bleeding may inaccurately assess the adequacy of tissue perfusion; it remains the most common method of flap blood supply evaluation [60].

Reconstructive surgeons are constantly looking for ways to improve free flap outcomes, as free flap loss can be catastrophic. Ideally, the surgeon could identify simple, reliable, and accurate adjunctive modalities that allow early intervention and limit postoperative complications. At this time no imaging modality has satisfied all of these criteria; however, as the use of promising innovative technologies such as intraoperative ICG angiography continue to grow and improve they could ultimately prove invaluable in decreasing complications due to ischemic causes.

(A)

(B)

(C)

Figure 10. Laser-assisted indocyanine green angiography. A) An initial low intensity signal is seen in the artery. B) A stronger intensity signal is seen in the artery to the flap as the ICG continues to be distributed throughout the vascular system. C) As blood containing ICG perfuses and exits the flap a signal is now seen in the vein.

Internal Mammary Lymph Nodes

Historically, the extended radical mastectomy involved axillary and internal mammary (IM) lymph node dissection with studies demonstrating a 20-30% incidence of IM nodal disease in breast cancer [61]. A randomized trial comparing radical mastectomy with

extended radical mastectomy demonstrated no significant survival benefit of an extended procedure that was associated with significant morbidity. They did however note the prognostic value of the IM nodes as mortality rates of IM nodal involvement alone was similar to that of axillary nodal involvement alone, while involvement of both locations was associated with a significantly higher mortality [62]. The dissection of IM nodes has since been largely abandoned. On the other hand, axillary lymph node disease is a well-established prognostic indicator and predictor of survival in breast cancer. Reports suggest that 20-30% of node negative patients will develop recurrence within 10 years compared to approximately 70% of those with axillary nodal disease [63]. Traditionally axillary nodal status was established by axillary lymph node dissections [64]. However, development of sentinel lymph node (SLN) biopsy, where the first lymph nodes receiving lymphatic drainage from the primary tumor are selectively sampled with radioactive or blue dye, has rapidly emerged as a less morbid alternative to axillary dissection. In fact, sentinel lymph node biopsy is now regarded as the standard of care in patients without clinical or radiographic evidence of nodal disease in early-stage breast cancer [64, 65].

As Halstedian mastectomies have now fallen out of favor for modified radical and total mastectomies, and imaging technologies have improved allowing for sentinel lymph node biopsies the question of IM nodal management has again presented itself. A recent study evaluating the rate of metastasis to the IM nodal basin and the clinical implications noted a visualization of IM SLNs in 22% of patients using preoperative lymphoscintigraphy. Of those nodes that were surgically removed, they noted that 25% were positive for metastatic disease. Clinically, based on tumor-positive IM SLNs, 7% of those patients that underwent IM SLN biopsy had a change in their treatment regimen of radiation or chemotherapy [66]. Internal mammary lymph node biopsy can be done through a parasternal incision at a selected intercostal space with or without partial rib removal. Given the low numbers of patients that require changes to their systemic or radiation therapy regimen, some consider the biopsy unnecessary [67]. As mentioned above, with decreasing axillary dissections the reconstructive surgeon has transitioned from use of axillary vessels to primary use of internal mammary vessels as recipient vessels for free flap breast reconstruction. During this procedure a partial rib resection is routine and IM lymph nodes are often immediately accessible. The senior author routinely samples these lymph nodes with no time added to the case and no additional morbidity. We contend that biopsy of these nodes is important and should not be overlooked. Ideally, the biopsied nodes provide more accurate staging of breast cancer. Particularly those patients with involvement of the IM nodes with no disease in the axillary nodes and no high-risk features that would indicate the need for systemic therapy or those without metastases to the IM nodes that would lead to sparing the potential toxicity of parasternal IM node irradiation would benefit the most [68]. In this manner the reconstructive surgeon not only contributes to the breast reconstruction, but to the oncologic treatment as well as the information obtained from the IM lymph node biopsy taken in the context of other clinical factors such as axillary node status, age, tumor features, etc. will help guide further adjuvant therapies needed beyond breast reconstruction.

⁴University Hospital Virgen del Rocío, Seville, Spain

ABSTRACT

Ambulatory surgery is constantly being updated, and is becoming more numerous interventions in this one day regime.

New materials and technological advances will certainly provide a large field of advantages for further proceedings in regimen of short-stay surgery.

New materials:

- Active Sutures: able to release substances at the site where they are applied. For example you sutures with antibiotics.
- Barbed Sutures (self-fixation): no need knotting, facilitating surgery and reducing surgical time.
- Self-gripping Meshes: no need of sutures or glues. This mesh improves the pain results. It reduces the surgical time.
- Biological synthetics meshes: useful in hernia repair and in perianal fistulae.
- Laser: useful in hemorrhoids and perianal fistulae.

New techniques:

- Laparoscopy and Open surgery in inguinal hernia repair: TEP, TAPP, using new meshes and barbed sutures, traumatic (absorbable and metallic tackers) and non-traumatic fixation (glues).
- Hernioplasty using new meshes: self-gripping, biological meshes
- Proctology interventions with laser: FILAC, HELP, LHP

All these advances in the surgery field, could improves the results in the ambulatory surgery in our centers. The main reasons are: minor surgical time, the rate of pain is very low, the discharge is in 6-8 hours after the intervention, the quick recovery and functional capacity to work, and the big satisfaction of the patients with these techniques.

Keywords: ambulatory, surgery, materials, devices, innovations, sutures, mesh, laparoscopy

NEW MATERIALS

1) Active Sutures

The sutures are the ones who have advanced in recent years, as the research focuses on finding new components that allow better absorption, less foreign body reaction and better integration with tissue. In addition to the synthesis of new products for sutures, they are trying to improve existing ones by adding substances to provide more resistance to the sutures.

It was well known to add antimicrobials such as triclosan to absorbable sutures polymer to increase the strength of sutures to infections. These active sutures prevented bacterial colonization and healing favored in an antiseptic environment. However, being described microbial resistance to triclosan, which new antiseptics are being investigated for covering sutures, such as chlorhexidine or short chain fatty acids. Both have proven effective in vitro for inhibition of bacterial growth and are harmless under biological conditions.

The short chain fatty acids are harmless substances used as preservatives in food and cosmetics. Their presence inhibits bacterial growth by creating a hostile environment for reproduction, yet is harmless to the native cell growth. Its low cost and absence of complications make it an ideal for creating active sutures to combat infection item.

Besides the addition of substances, it is improving in creating surfaces that hinder the development of infections. The discoveries of the ability of biofilm formation by pathogenic bacteria increased aggressiveness have put us on track for infection prevention can be done by preventing the formation of biofilm.

Figure 1. Active antibacterial suture: Vicryl Plus.

The last line of research is based on generating changes in the molecular structure of sutures to prevent bacterial growth. Nanotechnology, continuous development in other areas such as aerospace engineering or tele-communications, is allowing the appearance of

materials that change under certain physiological conditions, resulting in a nano-porous structure.

With high surface area for protein binding. Then biologically active molecules are bound to the surface of the suture for subsequent release *in vivo*. Protein binding can be Achieved Rapidly in the operating room, and the process can be ready to enable the incorporation of a wide range of other therapeutic molecules.

2) Self-Adhesions Sutures

The suture materials have been evolving throughout the years so that at the present time we have great amount of non-absorbable synthetic sutures as much absorbable, these last biopolymers with different times from absorption according to each necessity, as well as elastic sutures, impregnated in antiseptic substances, sutures that incorporate needles less and less traumatic and more and more and resistant... etc... in this epigraph we make mention to a special type of suture threads, the bearded sutures whose three-dimensional conformation presents a species of teeth or beards throughout its route (Figure 1) that once applied to the weave leaves the suture anchored preventing that the thread moves. Of this form they obtain that the approach of the edges is perfect and mainly, the benefit that seem to contribute is that they distribute the tension of the suture to length of all its extension.

Figure 2. Schedule of bearded suture.

This bearded self-fixing system allowing the suture material for tissue approximation, which eliminates a long and tedious step in wound closure, the making of knots to attach and secure the connection.

Figure 3.

The helically barbs distributes tension across the entire length of the wound or tissue being approximated and eliminate the need for interrupted suture or tying knots. In this way some new opportunities appears above all in that cases of stitches are more difficult allowing

surgeons to do things they could previously not do with traditional sutures, and, undoubtedly, making operating time shorter.

There are two main brands of bearded suture nowadays in the market: Quill™ Knotless Tissue-Closure Device and V-Loc™ Wound Closure Device.

- Quill™ Knotless Tissue-Closure Device represents a revolutionary technology in wound closure made possible by bidirectional fixation within the wound. Its patented design

The Quill™ device is available in sizes 4/0 to 2. The bidirectional Quill™ device is available in absorbable and non-absorbable materials and configurations including Monoderm™, PDO, Nylon and Polypropylene. The unidirectional Quill™ loop device is available in absorbable Monoderm™ and PDO configurations.

- V-Loc™ Wound Closure Device: it incorporates a double angle to the line marked by the base of the suture and the beard that, theoretically contributes takes more trustworthy and lasting anchorage.

The different types from sutures Pad™ are mentioned in the following table:

Figure 4. V-Loc (incorporate an eyelet to toughen the suture).

	V-Loc™ 90 device	V-Loc™ 180 device	V-Loc™ PBT Non-Absorbable Wound Closure Device
Tensile Strength	7 days, 90%; 14 days, 75%	7 days, 80%; 14 days, 75%; 21 days, 65%	Permanent
Absorption Profile	90-110 days	180 days	Permanent
Procedural Applications	Soft tissue approximation where support is required consistent with the absorption profile	Soft tissue approximation where support is required consistent with the absorption profile	Soft tissue approximation
Color	Undyed, violet	Clear, green	Blue
Composition	Glycolide, dioxanone and trimethylene carbonate	Copolymer of glycolic acid and trimethylene carbonate	Polybutester

3) Self-Gripping Meshes

In the last years we are attending to the birth of new prothesis devices for surgical treatment of abdominal wall pathology, that incorporate some measures like a three-dimensional conformation and a combination of biomaterials that confer an auto-adhesion capacity to them that makes unnecessary the use of fixation methods added.

They are in his majority, prothesis composed, elaborated from a base of polypropylene or polyester, both materials whose effectiveness is very well verified, and a biopolymer which is the one that support, of a way or another one, the anchorage capacity, without necessity to fix the prothesis with metallic tackers, stitches or biological glues, this reduces costs, operating time and risk of grabbing the nerve, with the consequent effect on the diminution of the postoperative pain.

In this sense, the mesh *Adhesix*[®], (*Laboratoires Cousin Biotech, Wervicq Sud, France*) one is made up of a layer of polypropylene and on her a mixture of two biopolymers, polyethylene glycol (PEG) and polyvinylpyrrolidone (PVP) that to the contact with the humidity and the corporal heat forms an hydrogel with adherent characteristics, the mesh has not adhesiveness in dry environment.

Equally, the mesh *Hi-Tex Contact*[®], (*Laboratoires Bioser, Montpellier, France*) made from a polyester base impregnated with alifatic polyurethane as a rough appendix is provided of a porous structure in 3D it accelerates its integration and colonization by the fibroblasts.

The Mesh *Parietene*[™] *Progrip*[™] (*Sofradim, Group Covidien® Trévoux, France*) is a partially absorbable mesh, of low molecular weight, composed of polypropylene monofilament and Polylactic Acid, this last as a shape of hooks which are inserted between the muscle fibers, allowing secure attachment from its inner surface, with less risk of mobilization of the hernia sac under the prosthesis.

Figure 5. Progrid mesh (self gripping mesh) in open surgery and for laparoscopic surgery.

4) Biological-Synthetics Meshes: Hernia Repair and in Perianal Fistulae

Hernia Repair

Biologic mesh development resulted from a search for a biomaterial that could address the problems associated with permanent synthetic mesh, including chronic inflammation and foreign body reaction, stiffness and fibrosis, and mesh infection. New biological or synthetics

absorbable meshes can be use in ambulatory surgery in order to decrease the pain, surgical time and infection associated with the surgery procedure.

Hernia Plug BIO-A polymer (Gore Bio-A; W. L. Gore and Associates, Flagstaff, Ariz): Hernia Plug is a porous fibrous structure composed of synthetic copolymer that is bioabsorbed in approximately six months. It is both biocompatible and nonantigenic. The GORE® BIO-A® Hernia Plug repairs hernia defects by promoting a well-organized tissue response, while markedly reducing chronic complications associated with permanent implants. The unique design of the plug serves as a scaffold to facilitate tissue generation, and is highly adaptable and easily tailored to create an optimal fit for the defect. Results in an experience multicentric for two years of follow-up show the GORE Bioabsorbable Hernia Plug with onlay mesh is effective with minimal short-term complications (3.6%) and minimal long-term pain (3% incidence of pain at two years).

Biologic Meshes: Given the high cost of most of these materials and the limited available data, biologic mesh should be used judiciously and only when permanent synthetic mesh is inappropriate, such as in the contaminated field.

Figure 6. Gore BioA- inguinal hernia plug.

Fistulae Repair

The anal fistula plug is a noncutting, sphincter-sparing technique. It has low morbidity and can be repeated if necessary. We can use this procedure in patients who has had prior drainage with a seton before placement of the plug. The anal fistula Plugs are in this moment: 1) treated porcine submucosa (Cook Biodesign; Cook Medical, Bloomington, Ind) 2) synthetic bioabsorbable polymer (Gore Bio-A; W. L. Gore and Associates, Flagstaff, Ariz)

The fistula tract should be curetted, and the external opening débrided deeply. The plug should be advanced in one direction (inside to outside) from the internal opening to the external opening.

The base of the plug is seated at the internal opening. We sutured the base to the internal opening with absorbable suture to close the internal opening over the plug. The excess plug at the external opening is removed with shears, and the external opening left open (such a natural drainage). Success rates have been reported in a range from 43% to 87%. In our

experience, around the 50% of the patients had good results with total resolution of the fistula.

Figure 7. Fistuale Plug Bio-A.

5) Laser in Proctology Procedures

Ambulatory surgery is in a constant development because, by its nature, requires that operating times are reduced and recovery occurs most easily, without postoperative complications and without hospital cares for the patient. In this sense, any innovation to perform safe surgery in less time and with a rapid recovery, is particularly susceptible to being included in outpatient surgery programs.

In proctology, the increased difficulty in performing ambulatory techniques is postoperative pain, since it is an extremely sensitive area. Most proctologic interventions also include a complete removal of tissue, which greatly increases the discomfort during recovery. In this sense, the use of proctologic laser allows first performing an occlusion to treat the pathology without removing it.

The laser proceeds very selectively to the lesion, minimally damaging adjacent tissues. It produces minimal tissue damage, so pain is drastically reduced or it even completely disappears after surgery. So has fewer side effects needless destruction of healthy tissue and inflammation.

Laser devices used in proctology are made of glass fiber optic, transmitting the pulse of laser light right in the area you need. Its minimum size prevents extensive manipulations on the surrounding tissues, allowing addressing areas inaccessible to conventional surgery, with greater assurance of results. The console device allows you to adjust the dose of energy transmitted in each incision and in total intervention, so that the desired results are calibrated exactly. The laser also produces the sealing of nerve terminals that conduct the sensation of pain, by which the patient suffers at all during the procedure.

The procedure is ambulatory and requires a minimum hospital stay, blood loss and anesthesia needed is reduced. After surgery, the individual who has gone through she should just stay a couple of hours in the hospital before going home.

The fiber system used is different according to the pathology. For perianal fistula is required of an optical fiber blunt and flexible, that does not generate false paths during surgery. To address an intermittent pulse laser and prolonged periodic moderate frequency. The fiber should be blunt to produce a circumferential burn to close the fistula tract and promotes the healing thereof, since the objective of this intervention is the sealing of the duct and eliminate chronic granulation tissue which remains active infection.

For the treatment of hemorrhoids, an optical fiber with change angular tip, higher precision is used and is capable of moving as a needle, with minimal trauma, within solid tissue. The laser pulse used should be intermittent, short period, with high frequency and high energy. These high-energy short pulses allow vascular occlusion by the hemorrhoid vessels blood clotting inside, with a solid seal that prevents vessel patency. If the pulses were of long duration, the heat transfer to the surroundings of the vessel could cause a painful and burn recovery worse.

NEW TECHNIQUES

1) Inguinal Hernia Repair

Surgical pathology of abdominal wall is one of the most frequent pathology operated by ambulatory surgery system.

Traditionally, main issue that surgeons keeping in mind had been the hernia relapse. A long time ago, this concern is relatively well managed, because of the new prothesis made of different biomaterials and tridimensional conformations which get a free-tension repair.

Once this objective could be considered obtained, the interest of surgical community all over the world has been deposited in other clinical aspects of quality assistance. For this reason, the most of actual researches are going deeply in new techniques that besides of being safe and effective could provide the maximum comfort, with less postoperative pain, in an efficient way from an economic point of view.

In that sense, new methods of fixation, self-fixation prosthesis and minimal invasive surgery play an important role.

a) Inguinal Hernioplasty Without Sutures

The new availability of prosthetics and biomaterials has allowed to invent ever more anatomical surgical repair techniques and concurrently, the fact of eliminating, or at least reducing, the need of additional fixation has had a big impact in improving the efficiency of major outpatient surgery units: on the one hand making shorter operative times in order to optimizing the operating room occupation, and on the other hand, minimizing the risk of nerve damage, reducing in that way the chances of postoperative pain, essential issue in cases where discharges of patients have to be established at an early stage.

Fixation with Biological Glues

We have disposable two kinds of biomaterials derivatives of cyanoacrylate and fibrin sealants.

The cyanocrylate have shown a high adhesive capacity with minimal inflammatory response, which added to the simplicity of management, its low cost and its so-called antibacterial properties, placed it at the head of the biological glues used for the fixation of prostheses in hernia surgery. They do not require a special conservation or a complex processing. Its mode of employment is limited to pour a few drops of product in strategic places where traditional suture stitches would be situated and allow to dry for few seconds.

Fibrin sealants are chemical compounds containing among other products: fibrinogen, fibronectin, factor XIII, and as VEGF, TGF-B, EGF and FGF growth factors. They produce a fibroblastic proliferation in the first moments after the placement of the mesh, which helps correct integration and an optimal final result. It has a cost significantly higher than the previous, and processing prior to their use which requires a deep knowledge of the product. In the case of heterologous fibrin sealants (*Tissucol*[®]) this means a correct conservation in cold, removing several minutes before use and follow the instructions in the commercial kit that involves a transfer of product to different syringes and continuous agitation. Its application above the mesh is not done directly, but through a propeller device that sprayed product.

In the case of autologous fibrin sealants (*Vivostat*[®]) the cost is even higher. This system involves the removal of a sample of blood from the patient, prior to surgery and its treatment in a special container that extracted from the patient's own fibrin. Its main advantage is the elimination of possible immunological reactions.

Self Fixating Prosthesis

Self fixating meshes more utilized in One-day surgery are the previously commented, *Adhesix*[®] and *Parietene*[™] *Progrip*[™].

The mesh *Parietene*[™] *Progrip*[™] (*Covidien*[®]) appears in three modalities, two of them of elliptical form, specially designed to adapt to the anatomy of the inguinal region, with an adjustable auto-adhesive lapel around the cord, either towards the left, or towards right. The third variant is a flat plate of 15x9 cm².

Figure 8. Progrip in laparoscopic TAPP.

It's easy to use, surgeons only have to complete the dissection of the anatomical area and put the mesh in correct orientation, making sure the spermatic cord is suitably rounded by the lapel, once done this, last step is make a soft pressure pushing down for a few seconds in

order to PLA grips taking place on the surface. After that, only rest closing muscular fascia, cellular subcutaneous tissue and skin above it.

Adhesix® mesh has four varieties about size and shape: one oval shape, and three specially designed for inguinal region, one of them completely plate and the other two types with an aperture for the spermatic cord placement.

Its use is similar to the one before described for Progrid®, but in this case the adhesiveness of the mesh depends in great measure of the humidity of the surface. It is so important checking the correct position of the mesh before starting the closure for avoiding undesirable movements of it.

b) Laparoscopy Surgery In Inguinal Hernia Repair: TEP, TAPP

The advantages of this method include less pain, smaller scars, and an ability to visualize both sides of the abdomen through a single approach. That being said, this is the preferred technique when there are hernias present on both sides. It is also preferred when a hernia has recurred following a prior repair, as the surgeon is able to dissect through non-scarred tissues in order to fix the defect.

The laparoscopic approach is ideal for patients who are obese, have recurrence from a prior open approach, have bilateral hernias, or require an operation that may result in a shorter convalescence (ambulatory surgery). All laparoscopic inguinal hernia repairs require placing mesh in the preperitoneal space to reinforce the myopectineal orifice. This was initially performed with a TAPP approach requiring initial entry into the abdominal cavity followed by division of the peritoneum and subsequent entry into the preperitoneal space. TAPP is preferred for patients with a large hernia or a prior infraumbilical abdominal incision because the contents of a large hernia can be assessed and reduced from the abdominal cavity, and scar tissue from a prior midline incision makes TEP entry more difficult due to adhesions.

TEP is the most cost-efficient technique in terms of outcome, and recovery / reinsertion in work. Although TEP is a demanding technique, with a longer learning curve than TAPP, the results in ambulatory surgery make it the most appropriate laparoscopic technique for a discharge on the same day (with high rates of security against TAPP, because there is no access to the intra-abdominal cavity).

Indications in the Table:

TEP versus TAPP		
Attributes	TAPP	TEP
Indications	Bilateral inguinal hernia	Bilateral inguinal hernia
	Recurrence from prior open inguinal hernia surgery with Mesh or TEP Surgery.	Reucurrence from prior open inguinal hernia surgery without Mesh.
	Prior Midline abdominal or preperitoneal surgery.	Smaller or normal unilateral hernia (fully reducible defect).
	Large, partially reducible hernias	
	Obese patient	
Common Complications	Bowel injury	Bleeding from injured epigastric vessels or corona mortis.
	Port site hernia	Incomplete hernia reduction
	Mesh exposure to bowel due to incomplete peritoneal closure or peritoneal tears (causing obstructions)	Small peritoneal tears (undetactable) with pneumoperitoneum (causing pain and avoiding ambulatory surgery)

2) Proctology Interventions with Laser

FILAC (FIstula LAser Closure)

The perianal fistula is mostly mild pathology of chronic tendency, so although most cases are not serious or present complications, the high recurrence rate and the difficulty of finding a definitive solution make it a condition that requires a careful treatment.

The usual treatment of perianal fistula has been performed in ambulatory surgical programs for years, because they are usually not painful or complicated treatments. Fistulotomy and traditional fistulectomy involve significant discomfort in the late postoperative period, because the healing of these wounds usually requires time, but not usually cause pain in the immediate postoperative period, since the effect of anesthesia adequately control these symptoms.

FILAC technique involves occlusion of the fistula energy emitted by a blunt laser fiber. The energy transmitted to the tissue inside the path causes scarring that is immediately after the emission of energy and which is produced by the coagulation of proteins usually granulation tissue filled the duct. For proper sealing, it is necessary to treat all abscesses that may exist and completely remove the remains of the fistulous tract infection. The recommended method to eliminate the infection is the placement of a drain placed between the internal and the external fistulous opening fistula orifice to cease issuing pus. This drain help us following placement of the fiber laser through the hole.

When the path is clean, you can proceed to sealing by laser, to be held from the internal fistula opening retreating toward the outer and never backwards, to prevent the formation of abscessed cavity and false ways to annul the effect of occlusion. If the internal fistulous chronic signs of granulation, the production of a small mucosal flap to reinforce the effect of the laser on the mucosa is recommended.

The laser pulses must be programmed into the device to be moderate, intermittent frequency and maintained timing. Fiber is slowly removed from inner hub to the outer, we left the checking successively closed by a soft tip reintroduction fiber path.

In the external fistulous opening any action may not be necessary, although some authors recommend excision circumferential external fistulous opening with monopolar scalpel, favoring the creation of a stronger and without chronic granulation tissue scar. The removal of surrounding tissue has not been shown to cause better results, but a slight increase postoperative pain, so it is only recommended in patients with fistulas very long evolution in which the external fistulous opening is large.

The FILAC has no contraindication size of the fistula or by location, since not require excision of tissue damage or cross brings many fewer complications than other more aggressive techniques. Can be used in e intersphinterics extrasphinterics fistulas, provided the path is well defined.

The main limitation of this technique are multiple perianal fistulas involving the difficulty in occluding fistulas branched, especially if you have not managed to track properly. In these cases, you can make partial occlusions localized paths to progressively decrease the size of the fistula and the roads that form, to meet with a single journey.

Figure 9. FILAC: in an extrasphinteric anal fistulae.

LHP

Venous occlusion hemorrhoid laser is effective for the treatment of this disease that prevents the main postoperative complication option: the pain of excision of tissue. In performing this technique, the hemorrhoidal package is not removed, leaving a wound, but it is coagulated and occluded under the mucosa as a solid callus prevents venous dilatation and consequent hemorrhoidal prolapse.

By leaving scar tissue included under the mucosa, is not indicated in patients with grade IV hemorrhoids bulky, since the excess tissue of these patients makes their removal is necessary to obtain a satisfactory result. The best indication of hemorrhoidal laser occlusion are patients with grade II-III hemorrhoids, especially those who have presented episodes of rectal bleeding not associated with prolapse or those who complain of pruritus ani.

The technique is performed in the operating room under general or spinal anesthesia, as it requires an anal dilation anoscope that allows control the process of hemorrhoidal occlusion. You can place the patient in a position to Seville knife or lithotomy. Postoperative not exceed the length of anesthetic recovery as surgical discomfort is minimal.

To occlusion, three or four small incisions are made in the base of each hemorrhoid pedicle going to try (usually in the anterior pedicle right, rear right and left side). These incisions are made in the mucocutaneous junction, on the anoderm, before you begin to glimpse the hemorrhoidal package. It is not necessary that the incisions maximum of 2 mm in length, and we only need the caliber of the laser fiber. The fiber should be introduced parallel to the anal canal, without going through the anal mucosa to prevent bleeding and even exceed the length of the hemorrhoidal plexus. From that point, the laser pulses which have previously been programmed into the console to be short, high-energy start.

The laser pulses are applied repetitively removing the fiber over the hemorrhoidal package and through the anoscope watching a hemorrhoid lie clotting integrity of the anal mucosa and the internal anal sphincter is maintained is performed.

If the technique is performed well, after occlusion must observe a discrete skin retraction anus into the anal canal and the absence of bleeding through surgical wounds. If you notice any bleeding, can coagulate using long laser pulses, assuming the burn could cause pain.

After recovery from anesthesia, the patient can be discharged. The most frequent postoperative discomfort usually appear after 48 hours after surgery, when the occlusion is more established and has triggered inflammatory response in the area.

Long term results are unknown for this technique and the real rate of recurrence as well. Detractors argue that the results are poor, considering that hemorrhoids treated are in moderate degrees, they should have final results regardless of the treatment applied. The reality is that no treatment has been shown definitively described to eradicate hemorrhoids, you always have a recurrence rate, and laser results has been no worse than other painful techniques.

HeLP

Besides hemorrhoidal vein occlusion we have described, the laser can be used to generate a selective hemorrhoidal artery occlusion, which devascularize hemorrhoids by cutting the blood flow. By high energy pulses coagulation arterial dilation hemorrhoidal limiting is achieved. It can be used as the sole method or associated with LHP.

To perform this technique, you must first locate the artery going to flirt. Devices that are marketed include ecodoppler system coupled to Anoscope to find the arterial pulse before I coagulate. The administration of laser energy will also be incorporated into the anoscope, which is much simpler power management at the required point.

Figure 10. Doppler detection of hemorrhoids artery and devascularization with laser.

It is important to locate 3-4 hemorrhoidal arteries occlude want because if the treatment is performed in part, recurrence is more likely to be a fine vascular network connected to each other. Given the difficulty of finding all packages (in patients with previous vascular problems, for example), a LHP procedure associated is a simple technique that does not require selective localization of blood vessels.

The recovery is in 3-4 hours after intervention, with no pain and major complications in follow-up. Total recovery (work and normal life) is usually complete within 24 hours.

Chapter 97

AMBULATORY SURGERY: ANESTHETIC MANAGEMENT AND COMPLICATIONS

Monica del-Rio-Vellosillo^{1,*} and Jose Javier Garcia-Medina^{2,†}

¹Department of Anesthesia, University Hospital Virgen de la Arrixaca,
El Palmar, Murcia, Spain

and Department of Ophthalmology and Optometry, University School of Medicine,
University of Murcia, Murcia, Spain

ABSTRACT

Many surgical procedures are performed by ambulatory surgery and account for around 60-70% of all surgical procedures.

The ideal anesthesia in an outpatient setting should offer a smooth, rapid onset of action, produce intraoperative amnesia and analgesia, provide optimal surgical conditions with short recovery times, and have no adverse effects.

One of the factors determining the speed of anesthesia recovery is the anesthetic technique used.

Although local and regional anesthetics are anesthetic techniques that are increasingly used for ambulatory surgery because they allow fast recovery, general anesthesia continues to be the most widely employed anesthetic technique.

Inhalation anesthesia is the cornerstone of modern anesthetic practice. New short-acting inhalation anesthetics (e.g., desflurane and sevoflurane) offer fast recovery from anesthesia. However, with the introduction of propofol and new supply systems (e.g., target-controlled infusion), interest in total intravenous anesthesia is growing.

Postoperative pain and vomiting are two factors that usually delay patient recovery and hospital discharge. Identifying those patients at greater risk of postoperative nausea and vomiting may help modify the anesthetic technique used and to use a suitable perioperative prophylaxis.

Older patients and those with a higher classification according to the American Society of Anesthesiologists are at increased risk of perioperative complications.

However, deaths related to ambulatory surgery or anesthesia are extremely rare. Some studies have described several complications, but only in 0.08% of cases: e.g., myocardial infarction, stroke, pulmonary embolism and respiratory failure.

The most frequent intraoperative complications are cardiovascular events, especially hypotension and hypertension. Other less frequent complications include bradycardia, tachycardia and arrhythmia.

Respiratory events are the second most frequent intraoperative complication, as the commonest are laryngospasm and bronchospasm. Other more unusual complications include apnea episodes, aspiration, pneumothorax and pulmonary edema.

The complexity of ambulatory surgical procedures is increasing, as is the morbidity of those patients operated as in an outpatient setting. So while selecting patients for ambulatory surgery, it is very important to minimize perioperative complications as much as possible.

INTRODUCTION

Ambulatory surgery is one of the main areas of anesthesia and surgical practice, and comprises between 60-70% of all procedures [1, 2]. The result of increased limited resources, together with a bigger older population, mean having to place much more emphasis on seeking efficiency and less economic expenditure in medical resources [1].

This type of surgery offers certain benefits for patients, besides monetary saving. It lowers the risk of nosocomial infections and allows patients to recover in a comfortable environment with their family without disrupting their daily routine, which facilitates the cure process and reduces postoperative discomfort [3]. As some authors have demonstrated, this situation is remarkable for the elderly as they suffer cognitive dysfunctions and stress events more often during the first weeks of the postoperative period [4].

Careful patient selection is important to avoid adverse perioperative events. The selection criteria are surgical-, anesthetic- based, and are related to each patient's characteristics and social environment [5, 6]. Surgical criteria include those patients who do not need any complex preoperative preparations, with no major anatomic or blood volume loss (< 500 mL), require simple postoperative care and no subsequent parenteral treatment, and whose postoperative pain is managed by oral pain medication. Anesthetic criteria include the surgical procedures lasting less than 90 minutes. Patients are catalogued according to the American Society of Anesthesiologists (ASA) I, II and stable III, and can also be considered ASA IV for surgical procedures with local anesthesia. As regards patient characteristics, they need to be cooperative, responsible and have the capacity to understand oral and written orders. Furthermore, the possibility of disposing of responsible adult care when allowed home and during the first 24 h of the postoperative period is also necessary.

One of the important factors that determines patient recovery speed is the anesthetic technique used [2]. Although the use of local and regional anesthesia is increasing in ambulatory surgery as they allow quick patient recovery [7], general anesthesia is still the most widely used anesthetic technique [8, 9]. With the development of new anesthetics drugs, the impulse of multimodal analgesia and antiemetic therapy has extended the ambulatory surgery field [1].

ANESTHETIC MANAGEMENT

The main goal of ambulatory surgery is to provide smooth surgical anesthesia with rapid onset of action that produces suitable analgesia and intraoperative amnesia. It should also provide quick emergence and recovery, rapid patient rotation at low cost to finally end in a safe hospital discharge with few adverse effects [10].

The quality of anesthetic management includes measures that do not cause further damage to patients, facilitates the best working conditions for surgeons, provides an optimal perioperative care and helps process algorithms to achieve the best clinical results [11].

New anesthetic techniques, short-term anesthetic drugs and analgesics, as well as the development of new anesthetic monitoring equipment, have contributed to make patient recovery quicker [1]. However, all these factors have combined to increase patient costs. Even so, the cost of anesthetic drugs is below 6% of perioperative costs [11]. These costs lower as they also follow economic benefits such as: being able to perform several surgical procedures in the same operative time; a shorter recovery process; fewer staffing requirements.

The choice of the anesthetic technique to be undertaken must be adapted to patient needs, and also to the kind of ambulatory surgery. Premedication, anesthetic, analgesic and antiemetic drugs, and the cardiovascular, hormonal and fluid therapy therapies used will influence the quick recovery of those patients who have undergone ambulatory surgery [12].

PREOPERATIVE MEDICATION

Premedication is administered to produce sedation, reduce anxiety, optimize intraoperative hemodynamic stability and cut postoperative side effects without prolonging recovery from anesthesia [13].

Benzodiazepines are the most frequently used drugs for this purpose since small doses improve the perioperative fast-tracking process by reducing anxiety and its complications, as well as improving patient comfort and satisfaction [14]. However, small doses of midazolam which provide anxiolysis and anterograde amnesia, could delay patients from being discharged [15]. Other drugs like β -blockers and α_2 -agonists, are becoming more popular due to their anesthetic and analgesic-sparing effects [16, 17].

Premedication with α_2 -agonists, clonidine and dexmedetomidine has been associated with a reduced use of opioid analgesics, postoperative nausea and vomiting (PONV), and intraoperative blood loss [17-19]. The inhibitory effects of these α_2 -agonists in the sympatho-adrenergic and hypothalamo-pituitary stress response provide glucose control in patients with type 2 diabetes and cut the incidence of ischemic heart disease after surgery [20-22].

β -blockers (e.g. atenolol and esmolol) suppress the increase in circulating catecholamines induced by surgery and prevent cardiovascular events in elderly patients. The anesthetic and analgesic-sparing effects of β -blockers in ambulatory surgery allow quick recovery from anesthesia and cut postoperative side effects (e.g. PONV) [23].

PERIPHERAL NERVE BLOCKADE

A peripheral nerve block (PNB) shares many features of an ideal anesthesia for ambulatory surgery, and provides surgical anesthesia and analgesia at the specific surgical intervention site with few side effects. Administration of long-term local anesthetics is an appealing anesthetic alternative for outpatients [24, 25], and provides a suitable anesthesia and prolonged postoperative analgesia [1].

Placement of perineural catheters with ultrasound guidance as opposed to neurostimulation has proved more effective for treating pain during the first 24 h [26]. Furthermore, ultrasound guidance cuts the number of punctures in patients, makes inserting the catheter much quicker, diminishes vascular punctures, and reduces failing blocks and patient discomfort [27, 28]. It is unclear and has not been scientifically determined whether ultrasound techniques minimize the volume of local anesthetic required besides other non ultrasound block techniques [29].

Determining the concentration of the local anesthetic to be used with this technique is important to strike a balance between pain relief and maintaining appropriate mobility of the operated limb since local anesthetics can affect motor function [30]. Yet for the time being, the optimal regime of the local anesthetic used remains unclear. It would appear that continuous perfusion of local anesthetic combined with on-demand patient-controlled boluses could maximize pain control, and there is some evidence that it improves safety of patients and improves side effects. However, the use of low local anesthetic concentrations does not always correlate with a lower degree of motor block [31-35].

Other drugs have been combined with local anesthetics to increase the speed with which the block begins, to prolong its duration, and to increase intensity and success, while the possibility of toxicity from local also lowers at the same time. Evidence-based studies support the combined use of epinephrine or clonidine together with local anesthetics to delay the systemic absorption of local anesthetics [36-38].

This anesthetic technique acts in a specific place, has few side effects, provides excellent surgical conditions, and a superior analgesia compared with systemic opioids. PNB also lowers the surgical stress response, consumption of opioids, and cuts the duration of stays in postanesthesia care units (PACU), and also the incidence of PONV. It can be used in patients with anticoagulant treatment, increases patient satisfaction and facilitates early patient discharge, besides cutting costs [39-48].

Although this anesthetic technique provides a high degree of satisfaction among the patients undergoing ambulatory surgery [25], the advantages of a single puncture of PNB are limited given the duration of long-term local anesthetics (10-24 h) [24-25]. After the resolution of PNB, postoperative pain management is often difficult and unsuitable in an ambulatory setting. In fact a high proportion of patients (22%) continue to suffer pain and require oral opioids for 7 days of the postoperative period.

This anesthetic technique also offers the possibility of placing perineural catheters for the home pump infusion of local anesthetics by providing patients with continuous analgesia to avoid side effects of oral opioids and to offer greater efficiency than these do [49]. So a continuous peripheral nerve block (CPNB) is a technique that prolongs the effect of local anesthetics at the specific site thanks to the possibility of continuing with the administration of local anesthetics, employing analgesia more profoundly, and avoiding the use of opioids

and the early regression of the analgesic block [24]. This technique is well-tolerated by patients as side effects, such as toxicity of local anesthetic, infection or permanent nerve damage [50], are infrequent. On occasion, catheters are difficult to remove due to knotting or looping around nervous structures [51, 52]. It is possible to perform this anesthetic technique in a wide range of surgical procedures for both upper and lower limbs: an interscalene block for shoulder surgery; a supraclavicular and infraclavicular block for surgery of the upper arm to the hand; a lumbar plexus block for hip surgery; a femoral nerve block for surgery of the femur and knee; a sciatic nerve block for the posterior thigh, lower leg and foot [41-44, 53].

However, the clear benefits of this technique to manage pain after ambulatory surgery must be balanced against the cost of the equipment and the resources required to manage these systems safely beyond a medical environment.

CENTRAL NEURAXIAL BLOCK

The introduction of atraumatic pencil-point needles with a small gauge has become an appropriate anesthetic technique with outpatients as it provides a quick, safe and profound surgical block, along with the single injection of small doses of local anesthetics [54].

Choice of local anesthetic type is unclear. Bupivacaine can delay the recovery of the motor function and cause urinary retention by delaying patients from being discharged. Nonetheless, some studies have used low doses of bupivacaine to achieve motor block recovery more quickly, which makes it suitable anesthesia [55]. Nowadays, selective spinal anesthesia is often carried out using minimum doses of intrathecal local anesthetic to anesthetize a specific area. In fact some studies have compared this technique with the use of desflurane, and have reported better postoperative pain control and cost effectiveness with spinal anesthesia [56].

Ropivacaine offers the advantage of producing a reduced motor block by allowing patients to start walking about faster than bupivacaine. However, intraoperative analgesia and muscle relaxation are suboptimal [57].

Short-acting local anesthetics, such as lidocaine, are associated with a higher incidence of transient neurological symptoms (TNSs), and their use in ambulatory surgery has declined [58].

Other short-acting local anesthetics, such as articaine, chloroprocaine, mepivacaine and prilocaine, have been used in ambulatory surgery successfully [59-63]. These local anesthetics are potentially beneficial because they [64]: 1) produce a motor block of shorter duration and less urinary retention compared with long-acting local anesthetics; 2) offer quick recovery; 3) provide a predictable hospital discharge time; 4) entail a reduced risk of transient neurologic symptoms (TNS) compared with lidocaine. Even so, more urinary retention has been described after administering prilocaine and the block is longer than with articaine, which delays patients from being discharged [65]. However, articaine produces faster recovery than prilocaine, although this does not seem to offer significant advantages compared to 2-chloroprocaine [66, 67]. Several studies have also suggested that the recovery time with 2-chloroprocaine is similar to general anesthesia. However, the use of this drug is not approved in all countries [68-72].

It is possible to add an opioid (e.g. fentanyl or sufentanyl) to the spinal anesthesia solution to reduce the side effects of local anesthetics, shorten patient recovery time and prolong analgesia [73]. This produces increased incidence of postoperative nausea and itching [74]. Another adjuvant used in spinal anesthesia is clonidine, but this combination can produce hypotension and prolong patient recovery [75, 76].

The use of epidural anesthesia with a continuous catheter might help control neuraxial block length in ambulatory surgery [1]. Some studies have suggested that epidural anesthesia is associated with less pain during the postoperative period, fewer interventions by nursing staff in the PACU, lower anesthesia costs and more hemodynamic stability [77]. Nonetheless, it has also been associated with prolonged anesthetic time, delays in discharging patients in short-acting surgeries and potential postoperative urinary retention, particularly in the elderly [3].

Although recovery after a central neuroaxial blockade has improved due to the use of low doses of local anesthetic combined with opioids (fentanyl), patient discharge is often unpredictable and prolonged by approximately 2-4 h after its administration in comparison to general or local anesthesia with sedation [1, 78-79].

A central neuroaxial block offers the benefits of being a simple, safe technique which provides suitable surgical anesthesia. Although it has been associated with prolonged induction times for surgery, they are shorter than with PNB. It has advantages over general anesthesia in terms of cutting the incidence of PONV and sedation [1]. Levels of pain are lower and the need to use opioids in PACU is smaller [80]. It does not cut long-term morbidity, but reduces neurological, cardiac and endocrine complications [81]. Spinal anesthesia as an epidural anesthesia may also lead to perioperative hypotension, postoperative urinary retention, postdural puncture headache, dizziness and delay in onset of walking [3, 82, 47].

GENERAL ANESTHESIA

An ideal general anesthesia technique should provide smooth, quick induction, optimum surgical intervention conditions and a quick recovery with minimum or null side effects [2].

Compared to other anesthetics or inhalations drugs, propofol, sevoflurane, desflurane and short-acting opioids, such as remifentanyl and fentanyl, produce an excellent anesthesia with quick recovery, and also reduce postoperative complications (e.g. respiratory complications, such as airway obstruction and hypoxemia) [83]. Discharge times after using these drugs are comparable with regional anesthesia [77]. Nevertheless, general anesthesia has a higher incidence of PONV and implies more costs [84, 85].

Given its unique recovery profile, propofol is considered the hypnotic of choice to anesthetic induction, although it is more expensive than inhalation anesthetics. Other potential benefits of this drug are antiemetic properties and lower incidence of euphoria and tremors on awakening from anesthesia [86]. However, the non irritant properties of sevoflurane also allow a smooth, quick inhalation anesthesia induction [87-89]. Inhalation anesthesia can be used as an alternative to intravenous induction with propofol and neuromuscular blocking agents if access to an intravenous line is difficult, patients fear needles or it is preferable to keep patients in spontaneous ventilation (e.g. patients with a difficult airway).

Inhalation anesthetics allow faster awakening, probably due to its easy titratability, and has some neuromuscular blocking effects, which could reduce the requirements of neuromuscular blocking agents [90]. Avoiding neuromuscular blocking agents helps good patient recovery. This is because a residual block may cause uncomfortable symptoms (visual disturbances, inability to sit down without support, facial or generalized weakness) which could delay patient discharge [91], and are usually noticed clinically. Furthermore, the use of sevoflurane can prove more economic than propofol infusion [85, 89, 92]. Even so, with the introduction of new delivery systems (e.g. target-controlled infusion), interest in total IV anesthesia (TIVA) is increasing [93]. When sevoflurane is used, the risk of postoperative emesis and worse patient satisfaction increases. This increase in PONV can delay patient discharge and generate an indirect increase in costs [94, 2].

In clinical terms, there are very few differences between desflurane and sevoflurane. Nonetheless, desflurane allows faster awakening from anesthesia, especially among the elderly and the obese [86]. Desflurane is not often used in ambulatory surgery because it causes cough and irritation in airways [95]. Desflurane is also associated with an increase in PONV compared with propofol. Combinations of antiemetic drugs, such as droperidol, metoclopramide and ondansetron, can lower the incidence of PONV when desflurane is employed [96].

Nitrous oxide is widely utilized in ambulatory surgery. It provides analgesia, reduces inhalation and intravenous anesthetic requirements, which are more expensive, and shortens recovery time. Its higher incidence in PONV has been recently challenged. So there is no convincing reason to avoid its use [86]. New technologies also contribute to fast anesthesia recovery, such as electroencephalographic bispectral index monitoring, which allows the titration of general anesthesia and reduces the amount of hypnotic (propofol or volatile) anesthetic used to maintain anesthesia, thereby facilitating early patient awakening [97-100]. Another monitor to measure anesthesia depth is middle latency auditory evoked potential response amplitudes and latency [101, 102]. It may speed up patient discharge, but has no effect on the amount of anesthetic used or emergence time when inhalation anesthesia is employed.

Remifentanyl has a short-acting duration that is independent of infusion duration. It offers improvement over preoperative analgesia and hemodynamic stability with no harmful effects on the patient awakening time, and this drug even shortens this time because it lowers the concentrations of other drugs used. Neither does it increase PONV as other long-acting opioids do. Providing postoperative rescue analgesia due to the absence of a residual analgesia must also be anticipated [86].

Neuromuscular blocking agents are used to ease endotracheal intubation and the surgical field. In ambulatory surgery, short-acting neuromuscular blocking agents (e.g. succinylcholine) or intermediate-acting neuromuscular blocking agents (e.g. rocuronium) should be considered [103, 104]. The use of sugammadex, a synthetic γ cyclodextrin, allows fast recovery from neuromuscular block after administering rocuronium by avoiding the anticholinergics side effects produced with atropine and neostigmine, or with glycopyrrolate and neostigmine. The latter combination is associated with less nausea and vomiting [105]. It also allows faster tracheal extubation and reduces the postoperative respiratory complications caused by residual muscle paralysis [106].

A laryngeal mask airway (LMA) is a useful, effective alternative to endotracheal intubation for airway management in general anesthesia for ambulatory surgery. Its use

reduces the incidence of postoperative sore throat, although no differences have been observed in anesthetic requirements, hospital discharge and the incidence of general side effects [107]. However, LMA is inadvisable in patients at risk of regurgitation (gastroesophageal reflux disease, hiatal hernia, prior gastric surgery, obesity), with pharyngeal or laryngeal pathology, or who present failing lung compliance.

SEDATION

The objective of sedation is to achieve hypnosis, anxiolysis and amnesia. Furthermore, we must maintain spontaneous patient breathing and avoid emesis. This requires a striking balance between comfort and patient safety, while preventing cardiovascular and respiratory commitment or delaying patient discharge [108].

Although sedation is often offered as a safer anesthetic technique than general anesthesia, this is not often the case as numerous articles on cardiovascular and respiratory adverse events after the sedation technique have been published [109].

It is accepted that the characteristics of an ideal agent for moderate sedation include rapid onset of action, quick recovery of cognitive and physical faculties following the procedure, and a predictable pharmacokinetic and pharmacodynamic profile.

IV sedatives include short-acting drugs such as propofol, benzodiazepines, ketamine, barbiturates, etomidate and dexmedetomidine. Inhalational agents include sevoflurane and nitrous oxide. Common opioids analgesics comprise fentanyl, remifentanyl and alfentanil [108, 109].

Many anesthesiologists use a combination of several drugs, and it is difficult to decide between an opioid and a hypnotic as the main drug components of sedation to perform painless sedation.

Sedation is used on many occasions as an adjuvant during the infiltration of local anesthesia or regional anesthesia. However, central nervous system, cardiovascular, and respiratory monitoring is necessary to ensure patient safety.

The success of sedation techniques depends on careful patient and procedure selection, patient preparation, appropriate monitoring, and attention to recovery and discharge.

COMPLICATIONS

Unanticipated hospital admissions after ambulatory surgery reflect intraoperative and postoperative complications, with frequency at around 0.3-1.4% [110]. The reason for higher frequency is for surgical complications (38±79%) [111]. In 10±26% of cases, it is due to anesthetic complications, and more frequently to PONV, somnolence or dizziness, and less commonly to aspiration. In 6-17% of cases, it is due to medial causes, a worsened basal clinic situation, like diabetes, angina and sleep apnea, or to postoperative complications, such as dysrhythmias, myocardial infarction or bronchospasm [111].

Patients who have been subjected to general anesthesia are at a 2-7-fold higher risk of hospital readmission. This is related to length of surgery and perioperative complications [1].

The more frequent causes of hospital readmission are bleeding, fever, infection, wound disruption, and urinary retention [1].

Deaths associated with ambulatory surgery or anesthesia are extremely rare [1]. Studies like that carried out by Warner et al. with 38 598 patients, found two deaths caused by myocardial infarction and two others owing to traffic accidents, at 30 days of ambulatory surgery [112]. Thirty-one cases (0.08%) suffered myocardial infarction, stroke, pulmonary embolism and respiratory failure [112].

With increased complexity in surgical procedures and greater patient comorbidity, the selection of patients for ambulatory surgery is a very important step because patients with cardiovascular and respiratory disease, obesity or smoking history are at increased risk of perioperative complications [113]. Old patients and a higher ASA stage are at risk of intraoperative side effects. Cardiovascular events are the commonest intraoperative side effect in ambulatory surgery [114], these being hypotension and hypertension with rhythm disturbances, such as bradycardia, tachycardia and arrhythmias, and they happen in approximately 1-2% of outpatients [114].

Respiratory disturbances are the second most frequent intraoperative side effect and occur in less than 1% of cases. Laryngospasm and bronchospasm, with or without desaturation, are the more frequent respiratory events. However, apnea episodes, aspiration, pneumothorax and pulmonary edema have also been described. Development relating to intubation (e.g. tooth damage or esophageal intubation) present a low incidence ($0.2 \pm 0.5\%$) [1].

Obese patients can have associated comorbidity with difficult venous access and airway maintenance, thus they present more postoperative complications [115].

Old patients are associated with an overall 'stiffening' of the heart and vascular system, as well as autonomic nervous system dysfunction, and are at higher risk of hypothermia. Lung compliance and vital capacity decline are important predictors of postoperative lung complications. The number of neurons and reduced cerebral perfusion with age predispose old patients to greater postoperative cognitive dysfunction. Such patients are more sensitive to the central depressant effects of anesthetic drugs. Deterioration of kidney and liver functions affects the metabolism and excretion of lots of drugs. Old people are also more vulnerable to suffer hypoglycemia episodes during the perioperative period [116].

Other complications might come into play, such as a prolonged hospital stay for several reasons. Postoperative pain, together with nausea and vomiting, are important factors that may prolong hospital stays or produce hospital readmission by 3-4 times [117]. Other side effects include cardiovascular events, dizziness or drowsiness, which also prolong hospital stays [1]. The best predictors of a prolonged hospital stay are intraoperative hemoglobin concentration and blood loss [118].

Postoperative stay duration correlates with the frequency of minor or moderately severe complications. These complications do not tend to require hospital admission, but frequently delay patient discharge. Hospital discharge criteria include stable vital signs, orientation, no pain, no nausea or vomiting, and a responsible attendant being available. In addition patients should be able to start walking about, diuresis should commence, and they should tolerate oral fluids. The use of scoring systems can help standardize care and minimize the risk of unanticipated admission. Several scoring systems are available for postanesthetic discharge, such as the Aldrete Scoring System, or the system designed by Chung and Chung in Toronto,

similar to Aldrete's system, which scores patients from 0 to 2 for the five main criteria prior to discharge [119].

General anesthesia is associated with a major incidence of nausea and vomiting (PONV) (10±50%), and certain more painful surgeries (nose, ear, throat, orthopedic and urological surgeries) will require a longer hospital stay [118, 120]. Several factors have been identified for PONV: female sex, history of PONV or motion sickness, nonsmoking status and use of postoperative opioids [121]. Other predictors include type of anesthesia, surgery lasting more than 60 min, major and laparoscopic gynecological surgery, laparoscopic cholecystectomy, intra-abdominal surgery, and middle-ear surgery [123-125]. Hypotension due to inadequate hydration, early walking and movement, and force fluid intake can increase the risk of PONV [126]. Strategies to cut the incidence of PONV include: 1) use of TIVA with propofol which reduces PONV by around 19% [12, 86, 127-131]; 2) use of nitrous oxide is a questioned risk factor of PONV, although it is not as significant as volatile anesthetic agents. Both propofol and inhalation anesthetic agent produce more emesis when they are used with nitrous oxide. No differences among isoflurane, desflurane and sevoflurane have been found for emesis. A drop in PONV by up to 12% has been described when nitrous oxide; 3) minimizing opioids lowers the risk of PONV. Infiltration of local anesthetics, and use of alternative non narcotic analgesics and multimodal anesthetic techniques will reduce the employment of opioid; 4) regional anesthesia is associated with a marked cut in the risk of PONV compared to inhalation-based general anesthesia, thus avoiding exposure to volatile anesthetics and narcotics; 5) minimizing the use of reversal drugs; 6) maintaining adequate patient hydration; 7) multimodal individualized antiemetic treatment

Therefore, identifying these patients will help achieve successful PONV control through a change in the anesthetic technique used, a lower basal risk and a suitable prophylaxis technique.

A wide variety of antiemetic drugs are available for treating PONV, including serotonin antagonists, steroids, dopamine antagonists. Other drugs include antihistamines, anticholinergics, sympathomimetics drugs and neurokinin-1 antagonists [132]. Use of sympatholytic drugs (e.g. esmolol, labetalol), agonist/antagonists, and even ketamine, to control transient autonomic responses during surgery, can reduce PONV because of their anesthetic and opioid-sparing effects [17, 133, 134].

Serotonin antagonists are drugs such as ondansetron, dolasetron, granisetron, and palonosetron. Ondansetron was the first to appear and is the most broadly studied one, whose most frequent side effects include headache, constipation and diarrhea. Doses of 4 mg administered 20-30 min before surgery and finishing the supply of a PONV prophylaxis between 4-6 h post-surgery are recommended [135].

Other drugs used to prevent PONV are steroids, such as dexamethasone. This drug has a slower onset of action, so its administration is recommended immediately after inducing anesthesia. Its exact mechanism is not completely known, although it is thought that steroids inhibit prostaglandin synthesis at the central level and allow endorphin release. It is recommended in doses of 4-8 mg [136, 137].

Among dopamine antagonists, droperidol and haloperidol produce an alpha blockade, so they could produce sedation and extrapyramidal symptoms. However, these side effects do not usually appear with small the doses administered to prevent PONV (0.625/1.25 mg) [135].

Of all these drugs that prevent PONV, the three most commonly used ones are ondansetron 4 mg, dexamethasone 4 mg, and droperidol 1.25 mg, which all have a similar effectiveness on preventing PONV, and the risk is cut up to 26% when any of them is used [127]. The use, or not, of these drugs, and their combination, depend on the risk factors presented by each patient. Hence treatment must be individualized since performing antiemetic prophylaxis in all patients may not be indicated due to the expense and side effects involved [127, 138, 139].

Managing pain with a multimodal approach will allow the better control of postoperative pain and will involve fewer side effects, such as those observed with certain drugs like opioids [140]. We must ensure that patients are discharged from hospital with good pain control.

The drugs used in multimodal analgesia tend to be non steroidal anti-inflammatory drugs (NSAIDs), beta-blockers, N-methyl D-aspartate (NMDA) inhibitors, steroids and alpha-2 agonists, or local anesthetics. Other techniques have also been used: non pharmacological techniques like transcutaneous electrical stimulation and transcutaneous acupoint electrical stimulation [1, 128, 141].

Regarding the use of morphine or fentanyl in ambulatory surgery, fentanyl offers a faster onset of action, but according to some published studies, it does not seem to be associated with faster patient discharge. Most patients required additional analgesia to control pain. However, morphine has been reported to produce better quality analgesia, but has been associated with a higher incidence of nausea and vomiting, especially after discharge [142].

Other factors that can delay patients from being discharged include: sore throat, headache, dizziness and drowsiness [143]. The incidence of sore throat is 12.1%, and this becomes higher with the use of an endotracheal tube compared to LMA (45.4% vs. 17.5%, respectively) [144]. Perioperative hydration with 20 mL/kg¹ of IV isotonic fluid produces fewer postoperative symptoms, like thirst, nausea, dizziness and drowsiness, for the first 24 h of the postoperative time [126].

AMBULATORY SURGERY IN ORTHOPAEDICS: PREVALENCE, COMPLICATIONS AND LONG-TERM OUTCOMES

Omar Faour Martín^{1,*} and Miguel Ángel Martín Ferrero²

¹Service of Traumatology and Orthopaedic Surgery,
Hospital of Ávila- Sacyl, Spain

²Service of Traumatology and Orthopaedic Surgery,
Clinic Universitary Hospital of Valladolid, Spain

ABSTRACT

The concept of day surgery is becoming an increasingly important part of elective surgery worldwide. Relentless pressures to cut costs may constrain clinical judgments regarding the most appropriate location for a patient's surgical care. Ambulatory surgery in Orthopaedics has shown in our institution to be able to provide good-quality service. There still seems to be potential to increase the proportion of these procedures. Therefore, surgeons and anaesthesiologists must strongly adhere to strict patient selection criteria in order to reduce complications in the immediate postoperative term. We expose a revision of more than 10.000 patients during the last twenty years following the protocols of our Ambulatory Surgery Unit. Major complications recorded in our revision were minimal without any mortal case. Unplanned overnight admission rate of 0.14 % was achieved and a high rate of ambulatory substitution in procedures studied was registered.

Keywords: Ambulatory, orthopaedics, surgery, procedures

* Corresponding Author's Email: ofmartin@msn.com.

1. INTRODUCTION

Orthopaedic surgery is the branch of surgery concerned with conditions involving the musculoskeletal system. In recent years, the prevalence of musculoskeletal procedures has drastically increased around the world. In this context, the notion of day surgery is becoming an increasingly important part of elective surgery worldwide [1]. Decreased healthcare costs, efficacy of operative care, patient's satisfaction, and dedicated staff are important factors that have led to an increase in its popularity.

Public health policies have promoted ambulatory surgery. This has been one of the most important and dynamic changes in medical care during the last decades. Many managers consider it as a way to increase and enhance access and control costs [2]. At this respect, it has been estimated that the costs for day-surgery procedures are 25–68% lower compared with inpatient care [3,4].

However, this large diffusion has occurred without the outcome assessments that are usually associated with such an important change in health care practices and policies [5]. The potential advantages of day-surgery practice disappear when patients require emergency care due to adverse events. In this respect, the data provided by Matilla et al. [6], after a thorough study of day surgery of all specialties in Finland, revealed rates of admission of 5.9% and readmission within 24 hours postoperatively of 0.1%. In other studies, unplanned admissions after ambulatory surgery were thought to occur in approximately 0.5% to 1.5% of cases [7,8]. Direct admissions from a day surgical unit during a five-year study [9] varied by service: 0.80% for gynecologic, 0.79% for orthopaedic and 0.57% for general surgery departments. The main reported risk factors for hospital admission were duration of the surgical procedure, general anesthesia, bleeding and uncontrolled pain.

2. OUR EXPERIENCE IN ORTHOPAEDICS DAY-SURGERY

In many centers, ambulatory procedures are considered the norm for programmed surgical treatments. Local structural and functional differences may explain the variation in outpatient surgery activity still seen between hospitals together with different patient and procedure-related selection criteria [10].

We have performed an updated of data registered previously of our experience in orthopaedic day surgery [11]. The centre is a teaching university hospital with a referral population of up to 300,000 people. It belongs to the National Health System, which provides free universal coverage and is financed through the resources of the Spanish Public Administration. The Orthopedic Academic Department has an Ambulatory Surgery Unit, composed of three consultants with independent functionality. Four to six surgical sessions are held each week. The upgrade comprises the incorporation of recent years so that the data of patients operated in this regime from June 1993 to November 2014 are collected.

Inclusion Criteria for Orthopaedic Day-Surgery

As in the previous years, the patient inclusion criteria for orthopaedic ambulatory surgery in our institution are considered as follows [12]:

- a) Patient comorbidities: the patients could not have any uncontrolled metabolic or psychiatric illness, drug addiction, coagulopathy, epilepsy, history of severe anesthetic complications, symptomatic cardiac disease six months previous to surgery, body mass index exceeding 30, or be undergoing anticoagulant treatment. We considered patients that were I and II or controlled III and IV status, according to the preoperative risk criteria established by the American Society of Anesthesiologists (ASA). Controlled arterial hypertension, stable chronic obstructive pulmonary disease and diabetes treated with oral agents were not considered as exclusion criteria.
- b) Social status of the patient: the patient needed an adequate family environment with an available telephone, no architectural obstacles, a responsible caregiver for the 24-48 hour postoperative period, easy land communication with a hospital, and needed to be over 18 months of age.
- c) Surgical technique: patients with no complex preoperative preparation, with little bleeding and mild physiological aggression were included. The postoperative period should have been managed without invasive procedures.
- d) Anesthesia: possibility of using a safe method that allowed for a fast recovery profile.

Discharge after Ambulatory Orthopaedic Surgery

Patients were discharged according to Korttila's criteria for day surgery [13]:

- Vital signs stable for at least 1 hour.
- Patient oriented to person, place, and time
- Able to tolerate orally administered fluids
- Able to void, to dress and to walk without assistance
- No more than minimal nausea or vomiting
- Absence of excessive pain and bleeding
- The patient must be discharged by both anesthetist and surgeon
- Written instructions for the postoperative period at home, including a contact place and a person who may be telephoned, need to be reinforced; presence of a responsible adult to escort patient.

The patient had to be able to swallow and cough as well, and explicit consent from the patient or the adult caregiver was necessary for discharge.

Preoperative and Immediate Postoperative Management

The day before surgery all patients were personally given detailed oral and written instructions to follow for the ambulatory procedure. Hospital contact phone numbers for any eventuality were given.

During the immediate postoperative period, patients were transferred to a recovery room and discharged whenever they met the criteria described above. In most of the cases, all drainages (if placed) were removed the day after the surgical procedure.

Checks were done by a home-hospital unit during the first 48 hours after discharge. This unit used a public phone to ask all the questions about the process. All patients were reviewed in the surgeon's office within 7 days of discharge.

A clinical evaluation, both in the preoperative period and one week after surgery, was performed using the SF36 questionnaire [14]. It contains 36 items in nine separate domains. Eight of these comprise two or more items and the final one has only one item. Each domain is computed to give a scaled score of 0-100. It was adapted for use in our country and is widely recommended as a tool for health status assessments in care settings [14]. Subjective satisfaction, scored from 0-10, was registered, as well as an actual comparative satisfaction study with a subgroup of patients operated on in an inpatient regime of the main processes. This latter group comprised patients operated on by orthopedic surgeons from our institution that work outside our ambulatory surgery unit. Patients that would not fulfill the inclusion criteria for outpatient surgery because of clinical reasons were excluded.

Updated Results

The sex distribution of the 11,355 patients evaluated was 4,326 males (38.2%) and 7029 females (61.8%). The mean age was 42.3 years (range 2-81). The age distribution was as follows: 69 patients younger than 15 years old (0.60%), 1,340 aged between 15 and 30 years (11.9%), 2135 between 30 to 45 years (18.7%), 3,997 between 45 and 60 years (35.1%), between 60 and 75 years 3213 (28.4%) and 601 patients (5.6%) over 75 years.

The number of patients that were living in rural areas was 1,851 (16.3%), compared to 9504 (83.7%) patients that inhabited urban areas.

ASA scores were distributed as follows: ASA I in 6132 cases (54.0 %), ASA II in 4,962 cases (43.7%), ASA III in 261 cases (2.3%) and no patients with ASA IV.

Intervened diseases represented a wide range of pathologies: knee arthroscopy for meniscus resection, meniscus suture, and anterior cruciate ligament (ACL) reconstruction, shoulder arthroscopy for rotator cuff repair, acromioplasty and instability treatment joint mobilization, removal of osteosynthesis material, excision of synovial cysts, opening of pulleys for trigger fingers, tenotomies, removal of external fixators, arthrodesis and arthroplasty of the fingers, osteosynthesis of hand fractures, fasciectomy for Dupuytren's disease, removal of foreign bodies, nerve decompression (carpal tunnel syndrome, Guyon's syndrome, cubital algoparesia in the elbow); excision of neuromas, amputation of fingers, correction of toe deformities (hallux valgus, hammer toes) fingernail operations, skin grafting, neurorrhaphy, nerve grafting, palliative surgery of peripheral nerve paralysis, tenorrhaphy and tenolysis.

Regional anesthesia was used in 8289 cases (73%), local anesthesia was used in 2,964 cases of (26.1%), and general anesthesia was used in 102 cases (0.9 %).

The average time of the intraoperative period, from patient entry to the theater until exit to the recovery postsurgical area, was 28 minutes (range 10-117). The average time the patient spent in the unit, from arrival to discharge, was 184 minutes (range 24-322).

No major complications were recorded. Only 16 patients (0.14 %) required overnight admission after surgery. The reasons for admission were suspected pneumothorax (two patients), lack of a responsible adult to accompany the patient (four patients), non-acceptance of discharge due to general discomfort (four patients), monitoring the vascular status of the toes where slow revascularization persisted two hours after surgery (four patients), and vomiting (four patients). The main characteristics of these 16 patients were: mean age of 70.4 years (range: 61-78); ASA grade III in 12 cases (75%) and grade II in four cases (25%); regional anesthesia had been administered in eight cases (50%) and general anesthesia in seven patients (42.9%). The mean surgical mean duration was 67 minutes (range 35-119).

59 patients (0.52%) left the hospital by ambulance due to the postoperative indication of not being able to bear weight on a lower limb. 147 patients needed attention at the emergency department during the first 24 hours after discharged (1.3%) because of pain (108 patients) or bleeding (39 patients), with four subsequent hospitalizations after shoulder arthroscopy, six because of knee pain and swelling after ACL reconstruction and one after arthroscopic knee arthrolysis.

During the first 48 hours after surgery, a medical consultation by phone was needed by 2124 patients (18.7%) due to discomfort (1020 patients), concerns regarding postoperative prescriptions (224 patients), or bleeding (880 patients). Most of these queries were sorted out by phone.

Painkillers were needed during a mean postoperative period of 5.2 days (range 1 -29). The following complications were recorded during the first clinical revision that took place seven days after surgery: superficial infections were found in seven patients, which resolved with outpatient care; a metacarpophalangeal prosthesis infection in a rheumatoid patient that required surgical revision; two deep infections in diabetic patients operated on for Dupuytren's disease, one of which needed amputation of the fifth finger; suture dehiscence in five patients, one of whom was diabetic; intra-articular hematoma due to suction drainage malfunction in seven patients. The number of patients requiring admission between postoperative 24 hours and 28 days after surgery was eight (0.06%).

Subjective outcomes made reference to those patients capable of understanding and answering the items of the SF-36 questionnaire (11299 patients, 99.5%). The results of the questionnaire revealed a significant improvement in the quality of life index in postoperative values as compared to the preoperative values ($p < 0.0001$), in all the items: *general health, limitation of activities, physical health problems, emotional health problems, social activities, pain, energy and emotions*

The mean satisfaction value for the management of all surgical procedures was of 8.64 / 10 (range 4-10). The results for satisfaction between in Day and inpatient surgery during the last five years did not show significant differences overall, so the ambulatory management of the procedure did not mean a decrease in patient satisfaction.

Quality Indicators

To sum up, our experience in Ambulatory Orthopedic Surgery has presented the following quality indicators:

- Unplanned overnight admission: 0.14 %
- Readmission rate within 24 hours: 0.09 %
- Readmission rate 1-28 days after discharge: 0.06 %
- Emergency room visits rate: 1.3%
- Cancellation of booked procedures: 1.51%
- Ambulatory Orthopedic Surgery / All elective surgeries of the orthopedic department for the period studied: 39.2 %.

Reasons of cancellation of booked procedures (164) were: acute illness in 114 cases (73.8%), decision by the patient in 18 cases (10.3%), and lack of surgical material in 32 cases (15.9%).

The substitution rate for different surgical interventions, defined as the number of ambulatory surgeries divided by all surgeries performed for a specific procedure [7], was as follows:

- *Carpal tunnel decompression: 97.2%*
- *Arthroscopic meniscectomy: 77,5%*
- *Acromioplasty / bursectomy:83.4%*
- *Hallux valgus correction:96.2%*
- *Rhizarthrosis surgery: 87.2%*
- *Osteosynthesis of hand and wrist bones: 87.3%*
- *Anterior cruciate ligament reconstruction: 36.4%*
- *Dupuytren disease:88.4%*
- *Arthroscopical Shoulder inestability repair: 42.7%*
- *Tenolysis of trigger fingers:98.9%*

The number of total ambulatory procedures without unplanned admission was of 11,320. The mean direct cost of day-admission in our institution during the last twenty years was of 375.4 Euros. The economic global results coming from the data registered in our revision indicate that the saving has been at least of 4, 2495,627 Euros.

3. PRESENT AND FUTURE

The aim of our actualization was to determine the clinical and quality indicators of our experience in Orthopedic Day Surgery in a revision of more than 11,000 patients during the last twenty years, mainly in relation to the unplanned overnight admission and readmission rates. Also we consider that the description of the main characteristics of the patients that experimented complications and the patient comparative satisfaction rate between the

ambulatory and non-ambulatory procedures is a fundamental issue. As such, our revision may provide a benchmark to evaluate future outpatient orthopedic surgery disposition rates. Clinical indicators from the SF-36 score revealed favorable outcomes in the immediate postoperative term. The results for satisfaction between in Day and inpatient surgery did not show significant differences, so the ambulatory management did not lead to a decrease in patient satisfaction.

Ambulatory surgery in Orthopedics has shown in our institution to be able to provide good-quality service, with high patient satisfaction. There still seems to be potential to increase the proportion of these procedures, and best practices should be sought. The efficacy and quality of the process itself requires further study. Figures for clinical indicators and the proportion of day surgery of all elective surgeries at individual hospitals, and nationally, should be made easily accessible for benchmarking and quality control with an automated reporting system. In future, day surgery should be the norm for elective surgery.

Assessment of quality of care is not only important for health control, but fundamental for the development of the expanding day-surgery service. Relentless pressures to cut costs and to provide services in the least costly setting may, in the absence of contrary evidence, constrain clinical judgments regarding the most appropriate location for a patient's surgical care [2].

Our patient selection criteria were rather uniform and in line with present-day recommendations [15]. In the future, the demand for day surgery in the increasing elderly population and in patients with notable comorbidities will undoubtedly increase. Therefore, surgeons and anesthesiologists must strongly adhere to those criteria in order to reduce complications in the immediate postoperative time [16]. Some of these risk factors may be proxies for surgical and/or case complexity; however, there is currently no generally accepted measure of procedure complexity.

Major complications in our review were minimal, and there were no deaths. Despite a controlled IV ASA risk was not considered as an exclusion criteria, no patient with this condition were registered due to a concomitant disease, such as coagulopathy or cardiopathy that excluded them from our study. Quality of care was measured by rates regarding with unplanned overnight admission, patient returns to hospital within 24 hours, admission within 24 hours and during the first month after surgery, and cancellation of booked procedures. Those outcomes have been lower than data shown by other studies about ambulatory surgery overall [16-19].

Efforts must be carrying out in the management of Ambulatory Surgery in Orthopedics in order to reduce the unplanned admission rates. In this way, a deep preoperative specific clinical evaluation must be performed closed in time to the intervention in order to detect conditions that contraindicate an ambulatory procedure. Operations must be performed as minimally invasive as possible and clear indications must be given to the patients during the first hours with a tight ambulatory follow-up.

As in other articles [17-19], pain and bleeding still continue being the most common reason of adverse events after ambulatory surgical procedures. In our experience, most of the patients needing unexpected overnight admission or readmission during the first 24 hours after surgery, presented an advanced age, ASA condition of III, or a considerable surgical duration.

In order to minimize complications in ambulatory surgery, we consider essential to act on factors influencing on immediate recovery, such as postoperative analgesia and anti-emetic

prophylaxis [20]. In the same way, dressing of the limbs after surgery is critical. An inappropriate choice or placement could cause important and serious adverse events, and it is necessary to avoid bandages that could create compression and vascular problems, such as a full plaster.

In addition, we have recorded a high replacement rate for procedures such as knee arthroscopy, osteosynthesis of the hand, or carpal tunnel decompression, when compared with other published studies that report these rates up to 83.1%, 70.7%, and 64.3% respectively [21].

Ambulatory surgery in Orthopaedics may be considered a present and future essential part of the management of the specialty. Units Ambulatory Surgery have, within the National Health System as well as in the private sector, a considerable development over the past fifteen years That lead to an increasing efficiency in the care of patients eligible for orthopaedic surgical procedures that previously were admitted in conventional hospital units. The relative novelty of this healthcare modality, its important dissemination, the diversity of organizational, structural and functional configurations must be taken into account. Its significant impact in terms of quality and patient safety, make this kind of Unit, as one of the elements of priority in health politics. Standard criteria of quality and safety should be developed and established, as well as its continuous evaluation. Support and management of ambulatory orthopaedic surgery in the framework of the objectives and quality plan of any National System of Health must be consolidated.

From the perspective of the quality and efficiency there is widespread consensus on the quality, safety and efficiency of ambulatory surgery as healthcare modality. There have been indicators to know the exact value of this type of healthcare service and its quality control. The most used ones are: cancellation of procedure, Adverse events (Same-day unplanned repeated surgery, Unplanned overnight stay, Emergency consultation, Readmission to hospital, Risk-adjusted complications index), Substitution Index, Ambulatory surgery index and Satisfaction Index and postoperative pain assessment.

Disadvantages of this type of surgery, such as failure to follow perioperative instructions, inability to be served by another competent person during convalescence, the impossibility to dispose of transportation to be connected to hospital or the worry and lack of patient trust, is significantly attenuated with good patient selection.

Advantages offered by ambulatory surgery are many because of it allows more individual attention and according to the needs of the patient, altering the minimum lifestyle and allowing less disability and return to work as quickly as possible in lot of cases. Besides, it avoids all the complications of hospitalization and reduce healthcare costs.

To ensure the proper functioning and quality of this surgical modality is essential a multidisciplinary coordination and training in the techniques and requirements of day surgery in staff to be practice it communication of all professionals who are part of it. The training of practice leaders in principles of root-cause analysis, quality improvement, and process redesign is also essential so that when they receive reports of safety concerns, they are able to analyze them and enact change. Provider organizations that recognize these challenges and respond to them will be ahead of the game as the spotlight is increasingly focused on care delivered not just by hospitals but by truly accountable care organizations in all settings of care.

The complications described are rare and mild, with a low rate of unexpected admissions, without any mortal case, and good satisfaction results and overall outcome with an optimal acceptance by all those involved.

Units of ambulatory surgery require a number of structural resources and equipment, which are mainly in relation to the characteristics of the scheduled clinical activity and the degree of autonomy with regard to existing resources of each hospital centre.

Given the consolidation and advancement of ambulatory surgery in Orthopaedics, it is considered that the structural conditions of the units should be targeted to meet the requirements in good standards and recommendations, giving priority to Autonomous Units over other designs. It should be noted that the design recommendations at this respect must include functional aspects and be adapted to each specific reality. Decisions regarding the practical structure of the ambulatory units must be dependent on the organizational form and specific management of each one, and adopted, in particular, taking into account the organization and management of human resources.

Day case surgery in Orthopaedics is a very important concept which can be used to reduce the waiting time for elective operations, and help clinicians and managers to prioritize and plan patient's treatments. It needs to be incorporated in healthcare policies designs in order to minimize the hospital stay and cost, and ultimately to increase productivity.

Chapter 99

ADVANCES IN SURGICAL PROCEDURES THYROID GOITRES: SURGERY FOR LARGE AND DIFFICULT GOITRES

Yassar A. Qureshi and Fiona McClenaghan

The Royal London Hospital, London, UK

ABSTRACT

Thyroidectomy for goitres can often be challenging, but this is especially apparent for large and difficult goitres. These can often reach very large sizes prior to surgical intervention, and may also extend into, and adhere to, surrounding structures. This makes the surgery more exigent, and increases the risk of damaging major structures inadvertently, including the recurrent laryngeal nerve and parathyroid glands. In this chapter, we describe the optimal pre-operative management, including essential imaging to assess the thyroid, and investigations necessary for careful operative planning. We describe the operation for such glands in a logical manner, and incorporate techniques and advances which make the surgery more straightforward, and allow the surgeon to carefully identify and preserve vital structures. Further, we describe how to approach specific complications resulting from surgery for large goitres, including both intra-operative techniques and post-operative care.

INTRODUCTION

“Can the thyroid in the state of enlargement be removed? Emphatically, experience answers no... every stroke of the knife will be followed by a torrent of blood and lucky if his victims lived long enough for him to finish his horrid butchery! No honest and sensible surgeon would ever engage in it.”

Samuel Gross, 1866

This famous quote by Samuel Gross, a US surgeon is, thankfully, rarely the case in contemporary thyroid surgery. However, the thyroid surgeon can certainly appreciate his exasperation at this form of surgery, owing to the very high risk and demanding nature of the operation. His particular reference to an enlarged thyroid gland, or goitre, makes it a more remarkable observation, as thyroid surgery for such a diseased thyroid is much more challenging and carries its own peculiar and significant risks.

The ancient Chinese first described large goitres as early as 2700 BC, but it was not until much later that the disease was understood. The Romans coined the term goitre, from the Latin 'gutter' or throat, and indeed, it was Julius Caesar who observed that goitres tended to be endemic in his conquered Gauls- a fact owing to the low iodine concentration in the local water.

Although herbal remedies, incantations and exorcisms were used not uncommonly for the treatment of goitres, surgery was first described in 952 AD. Ali Ibn Abbas, an Arab Physician, performed a successful excision of a goitre under opium sedation. In the 12th Century in Italy, surgeons continued to perform this operation, albeit with an incredibly high mortality rate. It was not until 1791 that a French Surgeon, Pierre Joseph Desault, refined the surgery, with some success, but mortality remained so high that the French Academy of Medicine took the drastic action of banning the operation in 1850. With future developments in the field of anaesthesia, antisepsis and surgical technology, the operation resumed, with improved outcomes. Although the words of Samuel Gross held true at the time, it should not be forgotten that the first Surgeon to achieve a Nobel Prize was Theodore Kocher, for his work on thyroid physiology and refinement of surgical technique for the goitre.

Surgery for large goitres can be challenging. Goitres may reach very large sizes, and will invariably, to some degree, distort anatomy, thus making dissection in correct tissue planes problematic. Vital structures may be more difficult to identify, making the risk of complications more pronounced. Furthermore, the sheer size of the goitre often means the surgery is longer, with more dissection than anticipated, and the goitres may encroach into seldom visited body cavities, such as the chest.

Careful operative planning and investigation is most useful in ensuring that an optimal operation is performed. Exposure is key to good dissection, and thus certain intra-operative techniques may allow better access to tissue planes. After such operations, the patient is, perhaps, more likely to suffer post-operative complications and protracted recovery, and so must be carefully monitored and reassessed, to ensure their good recovery and early discharge.

PRE-OPERATIVE PLANNING

Examination

A thorough examination of the patient should be performed by the operating surgeon. This is to ascertain the size of the goitre, and plan for the site of the incision to give optimal access. Large thyroid glands may be due to benign or malignant disease. This needs to be ascertained pre-operatively, often by a combination of radiological and histopathological investigations. The importance of delineating the diagnosis prior to the operation is because

malignant disease may require more extensive surgery to obtain clear margins, and may be associated with extended lymph node dissection. Although true for inflammatory disease too, malignant disease is often invasive into surrounding structures. Tissue planes may be disrupted and dissection more difficult. Indeed, if a sub-total or debulking operation is envisaged, for example to relieve compression of the airway, this should be determined pre-operatively, rather than in the midst of the operation.

On examination, local lymphadenopathy should be assessed for, and previous scars should be specifically looked for. In some cases, a re-do operation will need to be performed, which are typically more challenging, and previous scars will need to be incorporated into the new incision. This is to ensure both good access, but also a reasonable cosmetic outcome for the patient.

Ideally, if possible, it is better to operate on euthyroid patients, and hence a pre-operative review by an endocrinologist is beneficial. This will minimise peri-operative erratic thyroid function, and avoid a potential 'thyroid storm' during the operation. Calcium levels should also be checked to ensure normal parathyroid function. The vocal cords and voice quality should be checked independently, and the results documented. This is especially important given that 1% of the population will have a unilateral asymptomatic paralysis of the cord. Medical co-morbidity should be assessed and optimised, to ensure minimal peri-operative risk, and to enhance healing and recovery.

Radiological Investigation

Most patients presenting with thyroid problems will undergo an ultrasound scan as an initial radiological investigation. This will give an indication as to the size of the thyroid goitre, and its relationship to surrounding structures. However, if dealing with large goitres, a contrast enhanced computerised tomography (CT) scan is especially useful, as it will give significantly more detailed information regarding the dimensions of the thyroid. In, particular, it will also clearly show the proximity to surrounding vital structures, and show extension of the thyroid gland into the retrosternal space or the thoracic cavity. These factors will allow the surgeon to carefully plan for the operation, not only in terms of the incision, but also the best method to approach the dissection of the gland. Consistent landmarks such as the trachea and carotid sheath can be helpful to convey the radiological findings to the actual dissection. However, more slender structures such as the recurrent laryngeal nerve and parathyroid glands will not be seen radiologically; in the case of the latter, unless there is a concurrent parathyroid adenoma. A magnetic resonance imaging (MRI) scan provides similar detail to the CT scanning, and is preferred in some units.

Previous radiotherapy to the neck can cause tissue damage by inflammation and necrosis and even if surgery is many years later, tissue planes will be compromised, anatomy may be distorted, and healing may be protracted.

Anaesthetic Review

The anaesthetist should be familiar with difficult and shared airways, and review the patient prior to the operation. This is to familiarise oneself with the patient's medical history,

biochemical thyroid status and to perform an examination. Particular history of airway and respiratory disease should be elucidated, and any possibility of airway encroachment explored. The patient's oropharynx should be thoroughly assessed: this will allow better planning for anaesthesia and intubation. Any potential disease involvement of the trachea must be fully explored, as it should be borne in mind that longstanding involvement of the trachea by a goitre may be associated with tracheomalacia. Positional breathlessness, dysphagia, and stridor should be evaluated, if present. Rarely, a very large or retrosternal goitre may compress the superior vena cava.

For thyroid surgery, owing to the ever-present risks to the airway, a definitive airway for the extent of surgery should be performed. This would normally involve a cuffed endotracheal tube. Fibre-optic intubation may be useful in cases where there is some degree of airway obstruction. Indeed, a pre-operative tracheostomy may be required where complete airway obstruction is imminent. There is no specific guideline on the use of paralytic agents, but it may help in reducing laryngeal reflexes. A strong analgesic, such as remifentanyl, is often used, as apart from its analgesic effect, it contributes to a mild hypotension, thus aiding the minimisation of blood loss. Dexamethasone at induction may also contribute to reduced inflammation and oedema around the airway and dissection field.

INTRAOPERATIVE TECHNIQUE FOR GOITRE SURGERY

The normal thyroid gland lies at the anterior aspect of the neck. It has two lobes, normally about 5cm each in size, connected by a central isthmus overlying the trachea. Generally, the superior aspects of the lobes are narrow, and become broader inferiorly. Medially, the relations of each lobe are the larynx, trachea and oesophagus, anterolaterally the strap muscles and the sternocleidomastoid and posteriorly the carotid sheath. These relations are important to bear in mind when approaching a large thyroid. The gland itself is surrounded by a thin fibrous capsule, which extends over the trachea (the pre-trachea fascia) and laterally onto the carotid sheath. When a large goitre is encountered, it often extends laterally, displacing the carotid sheath, but if the goitre is secondary to an invasive disease, it may infiltrate into any surrounding structure.

Initial Operative Approach

The patient is positioned supine on the operative table, with the head in extension, which can be achieved by placing sand bags beneath the shoulders. The head is placed on a circular head ring, and the anaesthetist should ensure that they are content with the endotracheal tube positioning prior to the preparation and draping of the patient. Once an unencumbered sterile field is set up, the surgeon can mark the skin incision. This usually lies 2-3cms above the sternal notch, ideally in a skin crease. However, the exact site and extent of the skin incision may vary dependent on the size of the thyroid. Indeed, if a re-do operation is being performed, the old scar should be incorporated into the contemporary incision.

Once the skin and platysma is breached, the anterior jugular veins will be encountered, and if they are obscuring the operative field, can be ligated. Once flaps are raised, the

infrahyoid muscles are delineated, separated in the midline and the central portion of the thyroid gland exposed. The strap muscles are dissected off the thyroid lobes. This will expose the superior pole of the thyroid, which should be dissected off surrounding structures in the correct plane beneath its capsule. The dissection is within the sterno-laryngeal (or Joll's) triangle, constituting the midline, infrahyoid muscles and the superior thyroid pedicle. Once the superior pole and its vascular pedicle are secured, the remainder of the thyroid can be mobilised, and the inferior thyroid pole approached. The middle thyroid vein, draining into the internal jugular vein, should be identified and ligated, prior to inadvertent avulsion.

ANTEROLATERAL DISSECTION

The strap muscles form this relationship with the thyroid, and the surgeon will encounter first the sternothyroid, then the sternohyoid and the superior belly of the omohyoid. The pairs of strap muscles converge in the midline and separated to gain access to the thyroid gland. Division of these muscles may ease access in dissecting the superior lobe of the thyroid. It can be safely performed by dividing the sternothyroid and sternohyoid muscles transversely as close to their origin in the midline as possible, as the specific branches of the ansa cervicalis which innervate these muscles approach from inferiorly. The divided muscles can then be retracted superior-laterally to expose the large superior pole of the thyroid. After excision of the gland, continuity of the muscle edges can be restored using interrupted sutures.

Often, between the sternothyroid and sternohyoid muscles, there lies an avascular plane, dissection through which will enable the surgeon to reach the carotid sheath. Development of this plane may be sufficient to allow the superior pole to be safely mobilised. Indeed, the deeper sternothyroid may still be transected, but division of the sternohyoid can be altogether avoided.

When approaching the superior lobe where there is clear invasion into or toward the muscles, the surgeon can employ the 'back door to thyroid' approach. This involves dissection of the sternocleidomastoid off the strap muscles. A plane between the carotid sheath and the lateral aspect of the sternohyoid is then developed, which allows access to the thyroid gland. If required, the inferior belly of the omohyoid may be transected to allow further access. This technique allows access to the lateral aspect of the thyroid for dissection, and can aid the avoidance of a protracted and bloody dissection if there is thyroid invasion or encroachment laterally, as may be found in very large goitres, goitres secondary to malignancy or in recurrent multinodular goitre.

POSTERIOR DISSECTION AND THE PARATHYROID GLANDS

The large goitre tends to enlarge in this direction, and can push the carotid sheath from a posterior to a lateral relation. The carotid sheath transmits the common carotid artery, and laterally the internal jugular vein, with the vagus nerve lying in between. The ansa cervicalis, motor nerves which innervate ipsilateral strap muscles, lie anteriorly on the sheath.

As mentioned, dissection of the plane between the medial sheath and the thyroid aids the mobilisation of the large thyroid. Owing to the potential catastrophe of injury to the carotid sheath structures, dissection around this relation should be slow and careful. If thyroid disease is invading onto the sheath, then the sheath can be carefully dissected off immediately above the underlying vessels.

The parathyroid glands, two superior and two inferior, will also be encountered during posterior dissection of the thyroid. The position of the parathyroid glands is not always consistent, and they may be located either outside or within the thyroid capsule, or in 0.2% of cases deep within the thyroid parenchyma. [1] The superior parathyroid glands, which arise from the fourth branchial pouch, are more consistently located, with most posterior to the superior thyroid pole. The inferior glands, arising from the third pouch, are often more variably located, but generally should lie around the lower thyroid pole. Normal parathyroid glands are only 5mm in size and often difficult to identify, particularly in a bloody dissection field. However, their identification and preservation is of utmost importance in good surgical practise. Interestingly, even with very large goitres, the non-ectopic parathyroid glands are consistently located within the expected field of variation. Pre-operatively, parathyroid glands, unless aberrantly large, will seldom be seen on ultrasonography or cross-sectional imaging.

The superior parathyroid glands lie superior to the inferior thyroid artery, on the posterolateral aspect of the thyroid gland. When dissecting the pre-tracheal fascia off the thyroid from a lateral to medial direction, the superior parathyroids will become apparent, and will most often lie deep to the recurrent laryngeal nerve.

The inferior parathyroid glands lie below the inferior thyroid artery, and are generally more anterior than the recurrent laryngeal nerve. Again, when dissecting the inferior pole of the thyroid, these will become apparent as the surgeon comes from lateral to medial, whilst the thyroid is lifted to visualise its posterior aspect. [1, 2]

Rather than inadvertent excision, the more common cause of parathyroid function failure after thyroid surgery is the devascularisation of the parathyroid glands. This can easily be caused by rough dissection, inadequate field of vision, or mass ligation of vessels. In 80% of cases, the parathyroids will receive an arterial blood supply from branches originating from the inferior thyroid artery. Regardless of the size of the goitre, this pivotal vessel and its immediate surroundings should be clearly visualised. To avoid devascularisation of the parathyroids, rather than ligate the main trunk of the inferior thyroid artery, only its terminal branches on the pre-tracheal fascia of the thyroid capsule should be ligated. This will ensure reasonable blood supply to the parathyroid glands and avoid post-operative hypocalcaemia. In the circumstance where the parathyroid glands are embedded within the thyroid parenchyma, a peri-capsular dissection can be performed, whereby a cuff of thyroid tissue is left attached to parathyroid to avoid vascular injury to the parathyroid gland.

In absolutely unavoidable situations, if the parathyroids are not all accounted for prior to excision of the thyroid gland, then the specimen must be examined.

The parathyroid glands, if salvageable, can be cut into small pieces and implanted into a small pocket fashioned in the sternocleidomastoid muscle. This scenario may be encountered, for example, when performing a curative resection for malignant disease which is infiltrating into or around the parathyroid glands.

MEDIAL DISSECTION AND THE RECURRENT LARYNGEAL NERVE

Medially, the surgeon will encounter the larynx and trachea. The thyroid goitre which is applied to these structures can be gently dissected off. If there is invasion into the trachea, then a small cuff may be excised with a primary suture repair performed, but dissecting into the larynx is more haphazard owing to the presence of the vocal cords and their nerves. Dissection must remain on the thyroid capsule at this border, and must only be conducted once the recurrent laryngeal nerves and the parathyroid glands have been clearly identified: this is perhaps the most crucial part of a thyroidectomy.

The external laryngeal nerve is a branch of the superior laryngeal nerve, which in turns originates from the vagus. It innervates the cricothyroid muscle, damage to which affects the quality and tonality of phonation. It lies anterior and medial to the superior thyroid artery, although in 20% of people it is intertwined within branches of the artery. [3] It is thus necessary that the superior pole of the thyroid is dissected completely free and the superior thyroid vascular pedicle appropriately visualised. For large goitres, as mentioned previously, transection of the strap muscles, particularly the sternothyroid, would aid in obtaining access to the superior pole of the thyroid. Further, the ligation of the superior thyroid artery should be precise, to ensure that the nerve is not inadvertently divided.

The most critical aspect of a thyroidectomy, made more difficult by large goitres, is the identification and preservation of the recurrent laryngeal nerve. Its inadvertent iatrogenic injury will have significant impact on the patient's quality of life; indeed, bilateral injury to the nerve can be life-threatening. Knowledge of the anatomy of the nerve is paramount, including its aberrations: indeed, the right and left recurrent laryngeal nerves run a different course. At the root of the neck, the right vagus gives off its right recurrent laryngeal branch. It winds around the subclavian artery and emerges behind the common carotid artery. Here, it takes a medial course and enters the right trachea-oesophageal groove. The left recurrent laryngeal nerve originates from the left vagus just lateral to the aortic arch, which it winds around to emerge medially into the left trachea-oesophageal groove. Once in the groove, the nerves ascend and pass either through or behind the ligament of Berry and into the larynx. This ligament is where the pre-tracheal fascia condenses between the thyroid and the anteromedial trachea. [3, 4] Division or ligation of the ligament here will undoubtedly injure the nerves. Care must be taken when dissecting the superior pole of the thyroid around the cricothyroid muscle, where either inadvertent damage to the ligament of Berry, nerve, or the muscle itself, can affect vocal cord function.

The inferior thyroid artery provides a most useful landmark when identifying the nerve. Although the exact relationship between the two is not always consistent, they can be identified in the same vicinity. The nerve can run superficial to the artery (25% of patients), deep (50%) or intertwined between branches of the artery (25%). [4] The inferior pole of the thyroid is usually approached after the superior pole: anterior displacement of the superior lobe should give a clear view of the inferior pole, and dissection approached carefully from lateral to medial. Gentle lateral retraction of the carotid sheath will aid in exposure of the tissue planes where the nerve is located. Once the artery has been identified, with its pulsation, careful examination will reveal the nerve. This should be traced along its length all the way into the larynx. It should be dissected free with as minimal contact as possible in

order to avoid neuropraxia. Ligation of the inferior thyroid artery should be of its terminal branches, precisely and one at a time.

The incidence of a right non-recurrent laryngeal nerve is up to 0.7% of the population. Here, the nerve directly enters the larynx coming from behind the common carotid artery. Non-recurrent laryngeal nerves are much rarer on the left, affecting 0.04% of patients. Of further note, although the nerves lie in the trachea-oesophageal groove in 80% of patients, they may traverse in and out of the groove, or may be lying outside of it. [4] Hence, medial dissection of the thyroid off the trachea must be deferred until the nerve is elucidated for its entire course.

Very rarely, when performing surgery for large goitres, malignant disease, or where a re-operation is performed, there may be an anticipation of disease involving the recurrent laryngeal nerve. For example, the nerve may be infiltrated by disease, making it impossible to dissect. This needs to be carefully discussed with the patient pre-operatively; the consideration of sacrifice of the nerve for disease control is a decision to be made jointly by the surgeon and the patient. The latter should be made fully aware of the possible implications on their quality of life following such an intervention.

Intra-operative nerve monitoring is not yet mandatory, but many surgeons do utilise it. If used, it must be borne in mind that it is not a substitute for actual visualisation of the nerve in its anticipated anatomical location. Further, false readings may be apparent if there is an effect on the nerve from local anaesthesia or from a neuromuscular blockade from an agent administered by the anaesthetist. Indeed, the tracheal-laryngeal electrode may become displaced, giving a false-negative reading. However, if used appropriately, it can audibly confirm gross nerve continuity, but should still be used in conjunction with correct anatomical correlation.

Although the recurrent laryngeal nerve provides the surgeon with some degree of anxiety, careful dissection, avoidance of mass ligation, and a detailed knowledge of nerve anatomy is sufficient to avoid inadvertent injury. Surgery for large goitres can make anatomical identification more challenging, but if key principles are carefully adhered to, the nerve should not be at risk. Meticulous dissection of the thyroid lobes, in a bloodless field and in the correct planes, will allow the surgeon to encounter the nerves, and the parathyroid glands, with a clear view.

Retrosternal Goitre

Although first described in 1749 by Albrecht von Haller, the famous Swiss anatomist, the precise definition of a retrosternal goitre remains debated. Generally, however, it is taken to mean where greater than 50% of the thyroid mass lay in the mediastinum, or below the thoracic inlet. This may be an extension from a normally located cervical goitre, or more rarely an ectopically sited thyroid gland which grows *de novo*. The incidence varies geographically, ranging from between 2-19% of all thyroidectomies. [5, 6] The treatment for retrosternal goitre is extremely challenging, fraught with risk, and controversial; it most certainly is a distinct operation to a cervical thyroidectomy. We will briefly highlight some important points for this type of goitre.

The main clinical implications of retrosternal goitre are related to the pressure they exert on mediastinal structures. This can be primarily by the thyroid parenchyma itself, or from secondary events such as haemorrhage or malignant growth.

The common structures that are affected include the trachea and bronchus, oesophagus, the aortic arch, carotid artery and superior vena cava. In some instances, the goitre may extend over the pericardium and below the right atrium. Pre-operative planning with cross-sectional imaging is mandatory. The structures affected by the goitre need to be known prior to an operation, and if necessary, the aid of a cardiothoracic surgeon enlisted.

The approach to such goitres is mostly through a cervical incision, especially if they are relatively small, or only enter the very proximal mediastinum. If more extensive, then a partial or total median sternotomy (to the 4th intercostal space) is required. [6] This is particularly true if the goitre is abutting major vascular structures where there is a high risk of haemorrhage, if the goitre is largely positioned in the posterior mediastinum, or if the goitre is secondary to malignant disease.

The key phases of the operation, once the thyroid is exposed, is to ensure vascular control. This is true for the superior thyroid vessels, which can be safely ligated, but principally for larger vessels, such as the carotids or those around the aortic arch: proximal and distal control is advocated. This ensures that, in case of vascular injury, haemorrhage can be curtailed swiftly, and it also allows more confident dissection of the thyroid off these major vessels. The inferior thyroid vessels will still be located cervically, and the same principles as a standard thyroidectomy apply: care to avoid inadvertent injury to the recurrent laryngeal nerve, the careful ligation of its distal branches to avoid parathyroid gland devascularisation, and to carefully identify these structures prior to pursuing medial dissection. Where airway structures are involved by goitre, the anaesthetist must be kept fully alerted: if necessary, endobronchial ventilation instituted. Dissection of the gland is performed from superior to lateral to inferior, all the while applying gentle traction to help deliver the retrosternal portion of the gland into the wound.

The risks of a standard thyroidectomy, particularly parathyroid or recurrent laryngeal nerve injury, are magnified. This is sometimes because these structures are stretched or splayed into aberrant positions. Thus, the surgeon must very clearly identify these structures, moving to more normal anatomy and tracing them if necessary. It should be borne in mind that a torrential haemorrhage from the chest will unlikely be controlled by a cervical incision, and a sternotomy would thence be required. Patients, therefore, should be appropriately consented and fully informed of such risks. [6]

Lymph Node Dissection

For goitre secondary to malignancy, a lymph node harvest is advocated for both therapeutic and prognostic and staging purposes. Pre-operative assessment with MRI or Ultrasound Scanning is essential to be able to ascertain the degree of lymph node excision required.

Level VI neck dissection is most often performed for malignant disease, and such a harvest is aided by finding the recurrent laryngeal nerve in the low or mid-level of neck. It can then be traced superiorly, and the lymph nodes excised without jeopardising it. The thymus is included in the excision specimen, if possible. Lateral neck dissection tends to be

more straightforward, unless there is invasion into the carotid sheath. Level IV dissection should be performed with care, as the thoracic duct may be injured, particularly if the nodes are affected by disease, and thus will be adherent. [7]

In some centres, sentinel lymph node biopsy has been performed for some thyroid cancers, but as yet there is no suggestion of enhanced outcome or improved staging information gleaned from this procedure. Indeed, misplacement of blue dye may cause spread of the stain across the whole operating field, making dissection trickier!

POST-OPERATIVE CARE

The post-operative patient should, ideally, be nursed in area of direct observation, such as a high dependency unit at a 45 degree angle. Owing to the anatomical location of the thyroid and the field of dissection, airway compromise is an ever present threat, and should be specifically assessed for periodically.

Once the thyroid goitre is excised, prior to layered closure of the wound, a check and then re-check should be made to ensure haemostasis. A large expanding haematoma collecting in the wound can definitely cause airway compromise and is a surgical emergency. The thyroid is a very vascular organ, and bleeding should be controlled during the operation with precise suture ligation, clips or diathermy. At the end, the entire bed should be thoroughly assessed, using warm saline wash, to review and address any bleeding. Positioning the patient in the head-down position will aid in this. Furthermore, the anaesthetist can be asked to induce several val salva manoeuvres, which may highlight further bleeding. If there is a tear in the thyroid capsule during dissection of the goitre, then this should be repaired with a fine suture, to control bleeding and also to stop the dissemination of thyroid cells. A bloody operative field makes thyroid surgery far more difficult, especially around the nerves and parathyroid glands, in this quintessential plane based operation. Larger vessels, such as the common carotid or internal jugular very rarely are involved with disease. If encountered, dissection must be performed with great care, to avoid a potentially catastrophic haemorrhage, and to avoid post-operative neurological complications. The assistance of a vascular surgeon should be enlisted if there is any concern. Finally, prior to closure, a vacuum based drain (such as a Redivac®) may be left *in situ*, both to stop compression of the airway from a potential haematoma or inflammatory fluid, but also in order to monitor blood output in case of a large bleed. If a haematoma does develop post-operatively, with airway compromise, then the wound and deeper sutures should be immediately removed to allow the haematoma to escape. Re-bleeding should warrant an early re-exploration of the wound, and any bleeding points addressed. Often, there is no active bleeding found, but rather generalised ooze. In this instance, a haemostatic adjunct, such as Surgicel®, may be used. A vacuum based drain should be left in the wound after a re-operation for bleeding.

It is mandatory for the surgeon and his or her equipment to remain sterile until the patient is successfully extubated. This is in case of immediate airway compromise where an emergency tracheostomy may be required. Bilateral injury to the recurrent laryngeal nerve will cause such an airway compromise, but thankfully, this is very rare indeed. More common is a neuropraxia, and this would be diagnosed if the surgeon had clearly delineated and ensured continuity of the nerves at the time of the operation. An elective tracheostomy is

rarely required, unless there is very significant stenosis of the trachea. In the authors' experience, tracheomalacia is very rare, even after surgery for very large and longstanding goitres, and can be treated with a tracheal stent, rather than with a tracheostomy.

Unilateral recurrent laryngeal nerve injury or neuropraxia will cause a change or hoarseness in voice. A naso-endoscope should be performed to assess the vocal cords; neuropraxia will generally settle within a few weeks. If dysfunction persists, then early referral to a speech and language therapist may be of benefit. Of course, the patient should be fully counselled about the likely long-term effects of such an injury.

In the post-operative period, metabolic imbalances should be assessed for regularly, both clinically and by serum biochemical analysis. If a total thyroidectomy has been performed, then oral thyroxine is commenced, and serum concentrations monitored to ascertain the optimal dose. Serum calcium should be monitored regularly in the post-operative setting, as levels can fluctuate. At its worst, an imbalance in calcium homeostasis can cause cardiac dysfunction and arrest. Hypocalcaemia may be due to inadvertent excision of the parathyroid gland(s) or desvascularisation. For the latter cause, levels may improve over time. There is no set guideline on replacing calcium; rather this is based on local or even surgeon specific practise. Some centres place patients on calcium supplements pre-operatively. Most, however, will discharge patients after the operation on a short course of oral calcium supplements, regardless of the serum calcium or parathyroid hormone concentration. These serum analyses are continued in the outpatient setting until there is a consistent return to normal readings. If this is not achieved, then it may indicate permanent injury (after 6 months from surgery) to the parathyroid glands, and long-term replacement therapy is instituted. Intravenous calcium replacement is rarely required, and should be reserved for patients who either have a drastic drop in serum calcium concentration, or those who are symptomatic of hypocalcaemia.

CONCLUSION

Thyroid surgery for large goitres can be challenging, difficult and fraught with an increased risk of complications. However, it is this group of patients with thyroid disease- benign or malignant – who have large goitres that cause the most symptoms. Thus, they stand to benefit the most from surgical intervention. Detailed anatomical knowledge and adherence to safe dissection principles, along with some specific manoeuvres to improve access and visibility of the operative field, can render such operations a safe undertaking. Indeed, the surgeon, if competent and safe, may begin to enjoy these stimulating operations and the benefit the patient derives from them.

Chapter 100

ELECTRICAL STIMULATION FOR IMPROVING PHYSICAL FITNESS PRE- AND POSTOPERATIVELY AFTER ABDOMINAL SURGERY

Artur Marc Hernández*

Laboratory of Training Analysis and Optimization,
Sports Research Center, Miguel Hernández University,
Elche, Alicante, Spain

ABSTRACT

In the last few decades, surgical techniques have been developed in terms of safety and efficacy, however, abdominal surgery continues to present some disadvantages. On one hand, is not unusual that patients develop perioperative complications, which can lead to longer hospital stay, higher costs to health system or even the death of the patient. On the other hand, it achieves bed rest after surgery, which causes a decrease in muscle mass and muscle strength, and reduces cardiorespiratory fitness. As a consequence, the functional capacity of the patient decreases, so the patient's recovery is delayed.

At present there are numerous studies showing that physical fitness at the time of surgery is a significant factor that relates to postoperative complications, indicating that poor physical fitness is associated with these complications and slower recovery after surgery. Consequently, in order to prevent these disadvantages, patients need to improve their physical fitness prior to surgery. Although exercise is an effective method for achieving these improvements, in clinical setting, electrical stimulation has several advantages. In sedentary subjects or patients with a poor or impaired physical fitness, it allows strength levels and muscular mass to be increased in a short period of time. In addition, due to its application, no voluntary physical movement of the patient is required, it can be applied in bed rest conditions. In this case, it has been proven to maintain levels of strength, muscular mass and functional capacity, resulting in earlier postoperative recovery.

INTRODUCTION

Abdominal Surgery

Actually, the number of surgeries is increasing all over the world, especially in developed countries. It has been estimated that between 2004 and 2012, the number of surgeries performed has raised in a 33.6%, and becoming 312.9 million of surgeries performed in 2012 [1]. Among all these surgical procedures, abdominal surgery is one of the most frequently performed surgery, so that it represents 32.5% of the total surgeries [2]. Abdominal surgery refers to any procedure that implies the surgical management of the abdomen or any of the abdominal organs [3]. Abdominal surgery includes colorectal surgery, hepatic and renal transplant, gastrectomy, esophagectomy or bariatric surgery, among other procedures.

Traditionally, this procedure required opening the abdomen through a large incision, however, at present, technological advances have allowed new techniques to emerge, such as laparoscopy, which are less invasive. Compared to open surgery, the use of this approach has shown, among other benefits, a lower mortality rate [4–6], a decreasing number of perioperative complications [5, 7, 8] and an earlier postoperative recovery [9].

Despite the benefits obtained by laparoscopy, abdominal surgery might still present complications. It has been reported that nearly 35.6% of patients suffer from any type of complication after major abdominal surgery, with 20.8% of major complications, which require invasive treatment or admission to intensive care [10]. Another study that was conducted with approximately 466,000 patients, strengthen the latter percentage, concluding that the risk of suffering from one major postoperative complication after intra-abdominal surgery was 18.6% [11]. These complications may provoke great disadvantages. On one hand, it may raise the mortality rate after surgery [12], which in abdominal surgery ranges between 2.73 and 3.5% [2, 10]. For instance, Sabaté et al. established in their study that, among patients who presented postoperative pulmonary complications, mortality rate was around 24.4%, while patients who did not present this type of complication, mortality rate was only 1.2% [13]. On the other hand, these complications may lead to a higher hospital stay [12, 14–16] and the admission to intensive care [12]. Altogether, this lead to an increase in healthcare costs. Some studies have reported that, after major abdominal surgery, myocardial infarction increases the costs in approximately \$20,000 per patient [14], while pulmonary complications raise it in around \$28,000 [17].

Due to these reasons, it is necessary to detect, determine and understand factors that influence the perioperative complications, in order to decrease the risks of suffering them.

Abdominal Surgery Complications

As previously mentioned, it is not unusual that certain complications may occur after abdominal surgery. Among all of them, the most frequent are infections with 13.3% of cases [18], pulmonary complications with 5.8% of the total patients [19] and cardiac complications, which cause 1.4% of the mortality after major abdominal surgery [14].

There are certain factors that are going to influence on the possibility of developing postoperative complications. Some of them can not be modified, such as age [4, 16, 20], male

gender [4, 21] or history of cancer [20]. Nevertheless, there are some other factors, such as the presence of different comorbidities (hypertension, cardio-pathology or diabetes mellitus) [16, 22, 23], smoking [16, 20, 24], body mass index [20, 25], sarcopenia [26–28] and poor physical fitness [21, 22, 24, 29], which are modifiable factors.

Currently, factors related to physical fitness are becoming important on surgery, since they are highly associated with postoperative complications. In fact, some studies determine that these factors are the most strongly related to postoperative complications [21]. Therefore, the improvement of physical fitness may lead to a reduction of these complications and an earlier recovery after surgery.

PHYSICAL FITNESS

Physical fitness has been defined as “a state characterized by (a) an ability to perform daily activities with vigor, and (b) demonstration of traits and capacities that are associated with low risk of premature development of the hypokinetic diseases (i.e., those associated with physical inactivity)” [30]. In general, physical fitness is defined by different components. On one hand, the skill-related components refer to athletic capacities, as agility, power or coordination [31]. On the other hand, the health-related components, are integrated by cardiorespiratory and muscular endurance, muscle strength, body composition and flexibility [31]. Health-related components have a greater incidence on public health, since they are related to the health of individuals. For instance, cardiorespiratory fitness is inversely proportional to mortality [32], while a low muscular strength is directly proportional to premature death [33].

At this point, it is necessary to define several concepts referred to health-related components which are proved to influence on the results of abdominal surgery. In respect of body composition, it is highly remarkable its significant impact on health, since a high weight, especially a high body mass index, is related to different cardio metabolic pathologies [34], and the reduction of life expectancy. In fact, body mass index is associated with mortality risk [35]. Nonetheless, apart from the total weight, it is also important the body composition. Our organism is composed of different tissues (Figure 1), which have an influence on individuals’ health status, emphasizing two of them: fat mass and skeletal muscle. The former affects to health status, because an excess of it is related to health risks [36]. The latter, skeletal muscle, presents great benefits for health, since it is associated to an optimal functional capacity and is considered as a secretory organ. In this sense, skeletal muscle has different functions, such as absorbing 75% of the postprandial glucose [37] or releasing of myokines [38].

Here sarcopenia becomes particularly important. Sarcopenia is a syndrome that is characterized by a loss of skeletal muscle in addition to a decrease of muscle strength or performance, that develops into adverse results as poor quality of life or physical disability [40]. Although, both low muscle mass and low strength levels are independently associated with postoperative complications, when both conditions appear together, as sarcopenia’s case, the risk of suffering from any complication increases [26].

Data obtained from Dullo et al. [39].

Figure 1. Distribution of body tissues.

On the other hand, cardiorespiratory fitness makes reference to the capacity of circulatory and respiratory systems in order to provide fuel during physical activity [31]. Determining the cardiorespiratory fitness in patients undergoing abdominal surgery is really important, since it indicates the cardiorespiratory reserve that every patients disposes, and thus, it can be recognized the risk of suffering from any complication [41]. Cardiopulmonary exercise testing is a suitable method for determining this capacity [42]. This test allows numerous variables to be obtained, however, maximum oxygen uptake (VO_{2max}), peak oxygen uptake (VO_{2peak}) and anaerobic threshold are the most frequent variables for establishing relationships between cardiorespiratory fitness and postoperative complications. The VO_{2max} and VO_{2peak} define the maximum amount of oxygen that the patient is able to use, however it must be noticed that for being considered as VO_{2max} , it must have been produced a plateau in oxygen uptake [43]. In turn, when the oxygen provided to the muscles is not enough to cover the energy demands, anaerobic glycolysis intervenes transcendently to provide ATP, accumulating lactate exponentially, process known as anaerobic threshold [44].

Although cardiopulmonary exercise testing is the “gold standard” to determine cardiorespiratory fitness, sometimes, the necessary tools to perform this test are not available. Nevertheless, there are other type of measurements, as six-minute walk test, that can be used, since they establish functional capacity of the patients [43] and are also related to postoperative complications [45].

Role of Physical Fitness in Abdominal Surgery Complications

At present, physical fitness is considered itself as a factor of great importance in patients awaiting for abdominal surgery, since it may contribute to reduce perioperative complications.

First of all, there are factors related to muscular function. Sarcopenia has been proved to be really relevant, since it increases between 3.12 and 4.5 times the risk of suffering from postoperative complication [26, 27], so it is shown as an independent predictor of infection (odds ratio: 4.6) [46]. In fact, it has been reported that after colorectal cancer surgery, 23.1% of the patients with sarcopenia suffered from infections, while this data was reduced to 12.6% in patients without sarcopenia [46]. Furthermore, both the incidence of medical and total complications increase according to the level of sarcopenia (Figure 2) [47]. Nevertheless, components, that define sarcopenia (muscle mass and strength), are also related to postoperative complications. Patients with low muscle mass have 3.8 times more chances of suffering from postoperative complications, while patients with low strength levels have proved to have 2.1-2.5 more times of suffering from complications [21, 47].

Data obtained from Huang et al. [47].

Figure 2. Percentage of medical and total complications according to sarcopenia level.

On the other hand, cardiorespiratory fitness has proved to be especially significant in postoperative complications. Recent systematic reviews have shown that cardiorespiratory fitness predicts postoperative complications after different major abdominal surgeries, like hepatic transplant, abdominal aortic aneurysm repair, bariatric, upper gastrointestinal and colorectal surgery [12, 48, 49]. Furthermore studies have showed how anaerobic threshold and VO_{2peak} are powerful predictors for different disadvantages, as infections and pulmonary and cardiovascular complications [50]. For example, a VO_{2peak} lower than 15.8 for bariatric surgery and $16.7 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ for major colonic surgery [51, 52] is related to a higher number of complications and a longer hospital stay after bariatric surgery and major colonic surgery [51, 52]. Likewise, a $VO_{2peak} < 15 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ predicts mortality after abdominal aortic aneurysm repair [53]. Equally, anaerobic threshold range lower than 9,2-11,4 $\text{ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ predicts postoperative mortality and morbidity, as well as hospital stay and admission

to intensive care unit [54–57]. In addition, poor cardiorespiratory fitness affects to different complications. West et al. showed in their study that 16% and 23% of patients with an anaerobic threshold $< 10.1 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ presented pneumonia and infections after surgery, while in patients with a higher anaerobic threshold, these percentages decreased to 3% and 8%, respectively [52].

Besides, the risk of suffering from complications varies depending on different aspects. On one hand, a lower of cardiorespiratory fitness is associated with postoperative complications. It has been found that after major surgery, patients with a $\text{VO}_{2\text{peak}} > 20 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ have a low risk of suffering from complications, while patients with a $\text{VO}_{2\text{peak}} < 15 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ and $\text{VO}_{2\text{peak}} < 10 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ have a moderate and high risk, respectively [58]. On the other hand, these postoperative complications can aggravate if they are accompanied by comorbidities. A study conducted in “elderly patients” shows that, after major abdominal surgery, patients who presented an anaerobic threshold $< 11 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ showed a mortality of 18%, but patients who also presented preoperative ischemia, the mortality increased to 42%. In contrast, patients who presented the same morbidity, but with an anaerobic threshold $> 11 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$, the mortality rate was 0.8% and 4%, respectively [59].

After the data provided, it can be concluded that a poor physical fitness has a close relationship with postoperative complications. Both body composition and muscular and cardiorespiratory fitness are associated with postoperative complications, finding fewer complications in patients with greater fitness.

SURGICAL STRESS

In order to understand these associations between physical fitness and postoperative complications, it is necessary to know that surgery leads the human body to a state of stress that compromises the organism (surgical stress) [60].

The human body responds to the surgical process through different physiological pathways to maintain homeostasis, allowing cardiovascular, respiratory and metabolic changes. These changes are, among others, increases in cardiac output, heart rate, blood pressure, oxygen demand, and respiratory rate, as well as a mobilization of energy reserves to provide substrates as fuel to the repair processes of tissue and protein synthesis for the immune response [61, 62]. This will increase the risk of complications [61], therefore, it is necessary that the organism is prepared to deal with these physiological variations.

Surgical Stress and Physical Fitness

Physical fitness will determine the impact of surgical stress on the patient in different ways. After major surgery, there is an increase of 50% in oxygen consumption at rest, (from $110 \text{ ml}\cdot\text{min}^{-1}\cdot\text{m}^{-2}$ to $170 \text{ ml}\cdot\text{min}^{-1}\cdot\text{m}^{-2}$), which can be maintained for several days [63], and it is not strange that some patients reach an oxygen consumption of $240 \text{ ml}\cdot\text{min}^{-1}\cdot\text{m}^{-2}$ [59]. Consequently, these increases in oxygen demand will generate a deficit of it [45]. If the human body is not able to provide the oxygen necessary to respond to this O_2 deficit, different postoperative complications can be developed [45]. For example, one study showed that

patients who died after surgery had an oxygen deficit averaged at its maximum of $33.2 \text{ L}\cdot\text{m}^{-2}$, while this deficit was $21.6 \text{ L}\cdot\text{m}^{-2}$ in those who only had complications (without mortality) and $9.2 \text{ L}\cdot\text{m}^{-2}$ in patients who did not suffer any complications [64].

Therefore, it is likely that patients with an adequate cardiorespiratory reserve are able to resist this additional oxygen demand without exceeding their physiological parameters [49], thus reducing the probabilities of suffering from complications. This can be of great importance, especially in surgeries, such as liver transplants, in which there is a high mortality rate, around 10% [2]. In this regard, the cardiorespiratory capacity is so important, that only the increase in $1 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ of oxygen consumption at anaerobic threshold decreases the odds ratio of postoperative complications by 20%, while the increase of $2 \text{ ml}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ decreases it by 40% [52].

Likewise, skeletal muscle and muscle strength also seem to be important factors to resist successfully surgical stress. In patients with sarcopenia, a reduction in the expression of myocins is observed, which may decrease the activity of NK cells [65], increasing the risk of infection [21]. In fact, both sarcopenia and low levels of fat free mass are associated with the risk of infection after major surgery [46, 66]. For instance, after cardiac surgery, 18.5% of subjects with a low fat free mass index suffer from infectious complications, compared to 4.7% of subjects with a normal fat free mass index [66]. A reason could be that the amount of muscle mass is associated with the reserves of proteins available to the human body. Patients with low protein reserves have been associated with an increased risk of complications (especially pneumonia) and mortality after major abdominal surgery [67]. Thus, a larger amount of skeletal muscle indicates a greater reserve of muscle proteins, which are necessary to respond appropriately to surgical stress [68].

In addition, skeletal muscle could also play a relevant role in different metabolic aspects. Due to surgical stress, after surgery there is a large increase in blood glucose levels [69], which can be maintained for a few days. This can represent a drawback, since impaired fasting glucose is associated with perioperative cardiovascular events in patients undergoing major surgery [70]. Skeletal muscle is considered the largest store of glucose in the body, storing approximately 80% of glucose (around 500 grams) [71]. Therefore, it can be hypothesized that increasing muscle mass before surgery may provide a larger body's ability to store glycogen. This could prevent or reduce postoperative hyperglycemia, thus decreasing the problems associated with it.

Figure 3. Effects of preoperative fitness on surgical complications.

Relationship between Surgical Stress, Fitness and Recovery

Physical fitness plays a fundamental role in patient's recovery. After a major surgery, human body takes some time to recover functional capacity prior to surgery. After 3 weeks of colon resection surgery, only 41% of the patients showed equal or higher values of functional capacity compared to the preoperative levels [72]. However, patients who increase their functional capacity prior to surgery show an earlier recovery of walking capacity (Figure 4) [72]. For example, at two months of colorectal surgery, 81% of the patients who performed a prehabilitation program that included a part of exercise, recovered their functional capacity levels prior to surgery, compared to 40% of patients who did not perform this program [73].

Adapted from Santa Mina et al. [77]. 1, initial functional capacity; 2, functional threshold.

Figure 4. Effects of increase functional capacity prior to surgery on the functional recovery after surgery, theoretical model.

Both low levels of strength and muscle mass have been associated with a longer hospital stay after major surgery [66], therefore, it is necessary to reach surgery with these variables in an optimal state. Due to surgical stress, protein degradation is accelerated, in turn protein synthesis is low, which leads to a negative protein balance, causing the degradation of muscle tissue [62]. Moreover, abdominal surgery is followed by a period of inactivity, which causes losses of muscle mass and muscle function, and as a consequence, recovery after surgery would be delayed.

A study showed how, after only 10 days of bed rest, there was a reduction of 1.5 kg of lean mass, reducing by 6.3% lean body mass and by 15.6% muscle strength of lower extremity [74]. These values can be aggravated with admission to intensive care, since it has been reported that after 10 days, there have been reductions in rectus femoris cross-sectional area of 17.7%, observing that this loss increases proportionally with days of admission in intensive care [75]. Unfortunately, bed rest also causes decreases in cardiorespiratory fitness. In fact, it has been reported decreases of 7.6% and 15.3% of VO_{2peak} in young and older people, in just 2 weeks of bed rest [76].

ELECTRICAL STIMULATION AND PHYSICAL FITNESS

As has been observed, physical fitness is of great importance in abdominal surgeries. Improving physical fitness prior to surgery has two well-defined objectives. On one hand, to provide the organism with an adequate physiological reserve so it is able to cope with the stress induced by surgery. On the other hand, the improvement of physical fitness favors an earlier recovery. In turn, after surgery, a period of bed rest will occur, which will lead to muscle wasting and decrease the functional capacity of the patients.

Electrical stimulation has been shown as an optimal method to achieve improvements in physical fitness, especially in the clinical setting, where it is common to find sedentary or with a poor or impaired physical fitness patients. In addition, it is an effective treatment in bed rest conditions and in intensive care admissions, when voluntary exercise is not able to be applied.

Electrical stimulation is a non-invasive treatment that consists on the delivery of stimuli using electrodes that are placed on the skin [78]. There are different types of electrical stimulation, which vary according to their objectives: a) transcutaneous electrical nerve stimulation, which is used for treating acute and chronic pain conditions [79]; b) functional electrical stimulation, which aim is to help patients to perform a certain function, such as getting out of a chair [80]; c) neuromuscular electrical stimulation (NMES), which is used mainly during rehabilitation periods [81], being a useful tool to improve and maintain physical condition. Therefore, this chapter will focus on this last modality of electrical stimulation, due to the benefits that presents on physical fitness.

Effects of Neuromuscular Electrical Stimulation on Physical Fitness

Body Composition

The main advantage of NMES over body composition lies in its effects on skeletal muscle. To achieve increases in muscle mass by means of conventional resistance training, it is necessary to train with high loads around 60 - 80% of the maximum repetition [82]. However, many of the patients who are undergoing major surgery are sedentary subjects, which means that their body is not prepared to train at high intensities. To reduce the risk of injury, a period of anatomical adaptation before hypertrophy training should be carried out. However, NMES generates increases in muscle mass, especially in sedentary individuals [83], with the advantages that brings as a safe treatment, and therefore does not require such a long adaptation period. These characteristics make this method an effective alternative to use prior to surgery.

Regarding the intervention time that is necessary to achieve hypertrophy by NMES, although some studies have reported that it is possible to obtain hypertrophy in 4 weeks [84], most show that it takes around 8 weeks. Gondin et al. reported that after 4 weeks of NMES there were no significant increases in quadriceps cross-sectional area, finding significant gains after 8 weeks of training [85]. Likewise, other studies have shown increases of approximately 10% cross-sectional areal of the quadriceps femoris after 9 weeks of electrical stimulation in sedentary subjects [83].

One of the most remarkable advantages of NMES are its safety and effectiveness in patients with weakened muscles or under special situations, such as bed rest after surgery or admission in intensive care, where patients' physical fitness is reduced. At this point, NMES assumes particular relevance, since it avoids reductions in muscle mass [86]. For instance, it has been reported that after a period of 6-7 weeks of immobilization of the leg, the group that received treatment with NMES had a reduction of only 4.5% of quadriceps cross-sectional area, compared to a reduction of 17% of the group without treatment [87].

Unfortunately, some surgical complications result in a patient's admission to intensive care. In this situation, patients may have a reduction of up to 21.5% of sectional diameter of the vastus intermedius, however, in those who receive treatment through NMES, this loss is reduced by almost half, being 12.5% [88]. In addition, this is achieved safely, since the intervention by NMES in patients in intensive care does not cause increases in heart rate, blood pressure or O₂ saturation [89], indicating that it does not suppose a stressful treatment for the organism. Apart from that, NMES is considered a useful method to recover muscle mass during rehabilitation periods. In patients who have decreased their muscle mass, NMES has generated raises in the total area of the quadriceps (from 129.2 cm² to 142.2 cm²) after 12 weeks of intervention [90].

Although treating aspects focused on nutrition is not the objective of this chapter, it must be emphasized that in order to achieve the desired effects on muscle architecture (gain and maintenance of muscle mass), it is essential to have an adequate protein intake. To achieve increases in muscle mass it will be necessary to intake about 1.8 grams of protein per kilogram of weight, while the intake of 1.4 and 1.8 grams per kilograms of weight can prevent muscle protein catabolism, and therefore avoid the loss of muscle mass [91]. In fact, some studies recommend to take 25-30 grams of high-quality protein at each meal in order to minimize the loss of muscle mass during bed rest [92].

Muscle Strength and Functional Capacity

At present, it is widely accepted that NMES improves strength levels. The studies show increases of between 7.7% and 60% of the maximum dynamic force [83, 93], although it should be noted that the treatment must be carried out dynamically. Regarding isometric strength, these increases can reach up to 47.5% for the brachial biceps [94], 44% for the quadriceps [95], or 58% in abdominal strength [96]. Equally, NMES is effective for improving muscular endurance, showing increases of up to 243% after treatment [97]. Furthermore, these increases can be obtained in a short period of time. Although most studies last for 8 weeks or longer, shorter studies or intermediate evaluations also show positive effects on strength levels. For example, in only 2 weeks of treatment with NMES, there is 64% increase in muscular endurance [97], while after 5 weeks of treatment 33% increase in maximal isometric strength is achieved [93].

These benefits can be transferred to the clinical setting. Patients who are in a period of immobilization show a muscle strength loss of approximately 1.8% per day [86]. However, it has been widely accepted that NMES avoids or reduces the loss of strength in these situations, and also contributes to the recovery of strength levels during the rehabilitation period [98, 99]. Similarly, treatment with NMES avoids strength reductions in patients in intensive care [100], enabling a recovery of force 4.5 times faster compared to subjects who are not on treatment [101].

The loss of strength that will be generated after surgery will cause reductions in functional capacity [86], which is of vital importance to perform day-to-day activities. But NMES has also proved to be an adequate method to prevent these reductions. In adults with advanced disease, through 6 weeks of NMES the results in the six-minute walk test (+ 35 m), incremental shuttle walk test (+ 9 m) and endurance shuttle walk test (+ 64 m) are improved [102]. Likewise, patients in the rehabilitation period, where NMES was applied for 12 weeks, achieved a reduction in the time to perform the “sit to stand to sit” test and an improvement of approximately 10% of the six-minute walk test [103].

Cardiorespiratory Fitness

Many of the studies in which electrical stimulation is used for improving cardiorespiratory fitness are performed in combination with exercise, obtaining enhancements in VO_{2peak} [104, 105]. However, when electrical stimulation is applied in isolation, this technique does not seem to be so effective. Currently, this topic has been addressed by several meta-analyses. In one of them, it was determined that subjects who received NMES, achieved improvements in VO_{2peak} , but these were trivial (+ 0.10 L·min⁻¹) [106], while another meta-analysis showed that NMES did not produce increases in VO_{2peak} [102]. However, two important factors must be considered. On one hand, it is possible that parameters of NMES have not been correctly handled, and because of it, improvements have not been achieved. On the other hand, it should be noted that these analyzes were performed in patients who were clinically stable [106]. Possibly, NMES is effective in patients with poor or impaired cardiorespiratory fitness. As has been reported, after the application of NMES, healthy subjects only improved their functional endurance by 4%, however, clinical populations had improvements of 35% [107].

NMES presents different advantages in the clinical setting. First, it can be used for patients who are unable to exercise voluntarily. Apart from that, the movement caused by NMES is minimal, [108], in that way, it is unlikely to affect tissues that have been damaged during surgical intervention. Therefore, the use of NMES may be relevant to maintaining or increasing VO_{2peak} under clinical conditions, like bed rest or rehabilitation phase. For example, after cardiac transplant, through 8 weeks of NMES, VO_{2peak} was increased from 17.1 to 18.7 ml·kg⁻¹·min⁻¹ [109].

Limitations of Neuromuscular Electrical Stimulation

Nevertheless, treatment with NMES to improve physical fitness has some limitations, especially when compared to conventional exercise. First, the order of fiber recruitment. When a voluntary contraction occurs, small motor units (composed of slow fibers) are recruited in first place, and progressively larger motor units (composed of fast fibers) are recruited too [110]. This theory is known as “size principle” [110]. This order differs when electrical stimulation is used [98], presenting a disordered recruitment, stimulating both large and small motor units from the beginning [111]. This behaviour presents a great disadvantage. As large motor units are composed of fast fibers, that are more fatigable [112], NMES presents an earliest emergence of the fatigue compared to voluntary contraction [111].

Unfortunately, NMES has more drawbacks. This method is not able to activate all muscle fibers, activating those that are closest to the electrodes, that is to say, the superficial fibers, and not reaching the deepest ones [113]. In addition, by NMES, the same motor units are

always recruited, which will contribute to the emergence of early fatigue and therefore a decrease in torque [114]. Finally, when a voluntary contraction of a certain duration occurs, other muscle fibers are activated to replace those which are fatigued. This effect does not occur in NMES, in which the same muscle fibers are activated throughout the contraction (simultaneous recruitment), causing a greater fatigue [115].

All these factors will provoke that NMES causes great fatigue. On the other hand, for NMES to be effective, it is necessary to work at high intensities, reaching the threshold of pain, which will generate discomfort, reducing tolerance and adherence to treatment [116].

Maximal Voluntary Contraction

A fundamental concept in the NMES treatment is the maximal voluntary contraction (MVC), which is the maximum force that an individual is able to perform in a specific isometric exercise [117]. MVC is useful both to evaluate strength improvements after treatment with NMES and determine the intensity training. Therefore, NMES intensity training is the ratio between MVC force and NMES evoked force, expressed in percentage [118]. For example, if a subject has a maximum force of 200 Newton, and the treatment with NMES reaches 100 Newton, this means that subject is training at 50% of the MVC. An important aspect is that muscle activation increases linearly to the MVC percentage. In fact, even a formula has been proposed to determine quadriceps muscle cross-sectional area activated by NMES:

$$\text{Activated area (\%)} = 0.70 \cdot \% \text{ MVC} + 0.77 \text{ [119].}$$

The effectiveness of the NMES treatment depends on the MVC percentage at which training is carried out. It has been observed that if high muscle tension is achieved [120], the effects on hypertrophy improve. Equally, strength gains are associated with the intensity of treatment [121]. For instance, in one study it was reported that subjects who performed the treatment of NMES at 25% of the MVC, increased their strength levels by 24%, while subjects who reached 50% in the treatment had gains of 48% [122].

Parameters of Neuromuscular Electrical Stimulation

To optimize the treatment through NMES, several aspects must be considered. On one hand, high percentages of the MVC must be reached, trying to stimulate as many muscle fibers as possible. On the other hand, the appearance of fatigue must be minimized and the sensation of discomfort must be reduced. This will increase the torque during the sessions and let a greater tolerance and adherence to the treatment. In order to maximize the benefits of NMES, the different parameters that constitute this method must be manipulated correctly. In the following paragraphs, the most important parameters will be described (Figure 5).

Frequency

The frequency is expressed in Hertz (Hz), and refers to the “pulses” that are repeated in a second. As previously seen, to be effective, the treatment with NMES must cause a high percentage of the MVC, and this will increase with the frequency used. Unfortunately, the frequency is directly associated with the fatigue caused, observing that the higher the frequency used, the greater the fatigue obtained [123]. In fact, the frequency has been more

decisive in the appearance of fatigue compared to other parameters, such as current amplitude or pulse duration [124]. This will decrease the torque that is reached during the session, and therefore, the effectiveness of the treatment. It was observed that by applying a frequency of 100 Hz, the maximum torque was reduced by 76% at the end of the session, while by using a frequency of 25 Hz, the reduction was by 39% [124]. However, some authors have reported that working with frequencies lower than 50 Hz, tetanic contractions are not achieved, which is essential to generate benefits in muscle strength and muscle architecture [125]. In turn, too high frequencies will generate great fatigue, reducing the effectiveness of the treatment.

Nevertheless, when using high frequencies and occurring tetanic contractions, cardiovascular response is minimal, according to some authors, is approximately of 2 metabolic equivalents [126]. However, low frequencies produce sub-tetanic isometric muscle contractions, which generate a greater oxygen demand in the tissues [127]. Thereby, oxygen consumption raises and is able to reach into 53% of the VO_{2max} [128] or requires a cardiovascular response between 4 - 7 metabolic equivalents [127].

Adapted from Vivodtzev et al. [125].

Figure 5. Electrical current parameters and theoretical model of muscle tension evoked by electrical current.

Therefore, the frequency used will depend on the objective of the intervention. In order to maintain or recover skeletal muscle mass and muscle strength, it is recommended to apply frequencies between 50-120 Hz [98, 125, 129, 130]. On the contrary, to improve cardiorespiratory fitness, it is recommended to use low frequencies, between 4-10 Hz [108, 127, 128, 131], where 4 Hz frequencies has been proved to be especially effective [126].

Pulse Duration

Pulse duration, also known as pulse width is the duration of each current pulse, which is usually expressed in microseconds (μs). This parameter will influence directly the results of the treatment by electrical stimulation, since the higher the pulse duration applied, the greater the torque obtained [1]. For example, increasing the pulse duration from 150 to 450 μs

generates an increase of 40% of the muscle activation and enlarges torque by 55% [2]. In addition, a longer pulse duration will allow to recruit more fibers and reach deeper tissues, and it will be also useful when it is pursued to treat layers of secondary tissue [3]. However, too high pulse duration ($> 500 \mu\text{s}$) should not be used, since sensory nerve fibers will be recruited, which causes a large discomfort. On the contrary, too short pulse duration ($< 100 \mu\text{s}$) will not generate benefits [4]. This parameter manifests a great advantage. As long as it is within the appropriate ranges (between $150 - 500 \mu\text{s}$), the increases in pulse duration do not increase fatigue [5] and are well tolerated by subjects [6]. Thus, it allows more efficient interventions.

Lastly, some authors have reported that pulse duration will depend on the size of the muscles to be treated. For larger muscle groups, greater pulse duration ($> 300 \mu\text{s}$) should be used, whereas lower pulse duration ($100 - 300 \mu\text{s}$) are recommended for smaller muscle groups [7]. In summary, with the aim of achieving high muscular tension, with a low fatigue index, it has been recommended to use pulse duration between 100 and $500 \mu\text{s}$ [8, 9].

Duty Cycle

Duty cycle is the relation that exists between the time in which the stimulation is activated, that is, when muscle contraction is provoked, and the period in which it is deactivated. In the literature it is usually expressed in two different ways: a) as a ratio, for example 1:5, which means that muscle contraction is 1 second-long and resting time is 5 second-long; b) in percentage, for example 20% indicates that the stimulation is activated for 20% of a complete cycle. This parameter affects directly fatigue, and therefore, could reduce the effectiveness of the treatment. As the study by McLoda et al. showed, when using a duty cycle of 10%, the average of forced evoked was 132.9 Newton, while using a duty cycle of 90%, this average decreased to 41.3 Newton [132]. Equally, it can be observed how 72% of the subjects who used a duty cycle with a ratio of 1:1, decreased their initial force output by 50% in the first 10 minutes of electrical stimulation, while using a ratio of 1:5, only 6% of sample showed this fatigue [133]. Therefore, to reduce the fatigue caused by NMES within the same session, an effective strategy would be to extend the resting time in the duty cycle [134].

Nevertheless, duty cycle will be different depending on the desired objectives: a) to achieve increases in muscle mass, some authors recommend to use high duty cycles (1:1 or 1:2), with contractions of at least 2 seconds [120]; b) to obtain an increase in force, it must be used lower duty cycles, such as 1:5 [135]; c) concerning cardiorespiratory fitness, it is required high duty cycles, with ratios between 1:1 and 9:2 in order to obtain improvements [131, 136].

Amplitude

The amplitude is the intensity with which current is applied. It is usually expressed in milliamperes (mA), although sometimes it also appears in millivolts (mV). It is one of the most important parameters of electrical stimulation, since the torque produced increases linearly with amplitude [137]. In fact, according to some authors, muscle tension generated by amplitude is the greatest determinant of the effectiveness of NMES [138].

Treatment with high amplitudes has concrete advantages. NMES treatment stimulates the superficial muscle fibers, which are closer to the electrodes, observing how the recruitment of

fibers decreases when distanced from the electrodes [113]. However, when using higher amplitudes, apart from superficial fibers, deeper muscle fibers are depolarized, which are further from the electrodes [139]. As a result, a greater amplitude provokes a greater activation of the muscle and, therefore, a greater resulting torque [140], reaching higher percentages of the MVC [141]. In addition to obtaining a greater torque, the application of a higher amplitude will let the organism to enlarge the VO_{2max} . For instance, using an ~86 mA amplitude allows to reach 40% of the VO_{2max} , however, when rising amplitude to ~ 104 mA, it is achieved 53% of the VO_{2max} [108]. This intensity training has proved to be effective in improving cardiorespiratory fitness [128].

Furthermore, the amplitude has not been proved as a decisive parameter in the development of fatigue. For example, one study showed that frequency influences more than amplitude in fatigue [142], while it has been reported that increasing the amplitude enlarges the torque produced without increasing fatigue during NMES [124]. The major drawback of using high amplitudes resides in patient tolerance, since high amplitudes generate discomfort [143]. Therefore, the amplitude used depends on the tolerance of the patient [144], where it is recommended to apply the maximum amplitude that is tolerated in order to optimize the treatment [116].

There are different strategies that will help to increase tolerance and allow to train at higher amplitudes. In first place, training should not start using the highest amplitudes that the patient is able to bear, since this produces a certain degree of pain and discomfort, generating reticence of the patient to use electrical stimulation and, therefore, a low adherence [95]. Secondly, it must be considered that, at the beginning of NMES, the maximum amplitude that is tolerated increases rapidly during the first 10 days of treatment, after which a plateau occurs [145]. Therefore, before beginning a treatment with NMES, a period of 8-10 days of familiarization should be carried out. Thirdly, in order to maximize the effects of NMES, it is advisable to increase the intensity within the same session, since superficial muscle fibers (closer to the electrodes) can be fatigued [119]. As shown, increasing the amplitude allows stimulate deeper fibers, thus maintaining MCV levels [119].

Electrodes: Size and Location

Both size and location of the electrodes will determine the effectiveness of an NMES treatment. Firstly, the size of the electrodes is relevant in different aspects. Very small-sized electrodes will have a higher current density, which will increase the sensation of pain, generating discomfort [146]. On the contrary, large-sized electrodes are more comfortable, at the same time produce a greater torque [146]. However, the use of electrodes with an excessively large size should be avoided, since they could stimulate other muscles, which would lead to a loss of efficacy of the treatment [145].

Although there has been some debate about the location of the electrodes, it has already been reported that placing the electrodes on the motor point generates a greater torque, in addition to decreasing discomfort sensation [147]. The motor point is the region that covers the peripheral neuromuscular junctions, so it represents the closest area of the skin to the motor end-plates of the cross-sectional area of the muscle, which are highly excitable [98]. When placing the electrode on motor point, a less intense current is required in order to excite the motor axons and generate muscular contraction [148]. On the contrary, when placing the electrode in a point different from motor point, the intensity to reach the motor branch must

be greater, increasing the possibility of exciting sensory fibers, which transmit the pain (Figure 6) [148].

Adapted from Gobbo et al. [148]. MP, motor point.

Figure 6. Location of motor point.

Although currently there are atlas that indicate where the motor points of each muscle are located, the situation of these points is different for each subject [149], so it is necessary to locate them individually, which is quite simple. Only one pen-electrode is needed, with which the surface of the muscle is mapped until one concrete point is found. This point is the one that generates a contraction with the minimum possible current intensity [149]. In turn, the electrodes should be placed longitudinally with respect to the muscle fibers, because this position will generate a greater torque compared to transverse position [150].

Data obtained from Franz et al. [151] and Botter et al. [149].

Figure 7. Motor points for the upper and lower body.

Finally, some authors recommend, with the aim of activating other muscle fibers and minimizing fatigue, to change the electrodes of position, both in the same session and between different sessions [118]. Furthermore, as can be seen in Figure 7, a muscle may have several motor points that are going to activate different muscle portions [152]. This fact strengthens the usefulness of changing the position of the electrodes. While other authors have determined that using a greater number of electrodes will allow more motor fibers to be recruited, reducing fatigue [134].

Treatment Frequency

The frequency of the treatment through NMES also has an influence on the results. Although it seems that, 2-3 sessions per week are effective in order to achieve strength improvements, several studies have proved how gains increase with volume of treatment. For instance, 3 session training generated greater benefits compared to one of 2 times per week, while 5 session training caused higher gains of strength compared to one of 3 times per week.

In turn, to rise cardiorespiratory fitness, 5 sessions per week (1 hour/session) have proved to be especially effective [81, 127]. Furthermore, enhancements of the VO_{2peak} are significantly associated with training hours [128]. Then, it seems that a higher volume of training will increase the effectiveness of NMES.

CONCLUSION

Electrical stimulation is a method that offers great advantages in the clinical setting. It is a safe and effective treatment, especially for sedentary subjects. Within the types of electrical stimulation, NMES may be very useful in abdominal surgery, since it includes the following benefits: a) improves the physical fitness of patients prior to surgery, reducing the risk of postoperative complications; b) maintains physical fitness in bed rest conditions; c) allows the patient to increase the level of physical fitness faster, obtaining a patient's early recovery.

However, in order to obtain the highest effectiveness of the treatment, several aspects must be considered. First, the intended aim has to be defined. Second, electrical stimulation is composed of parameters that must be properly manipulated. The most relevant issues to maximize the benefits of the NMES treatment are:

- Training at high percentages of maximal voluntary contraction will generate a greater muscle activation, which provides larger benefits.
- To allow the patient to tolerate high intensities, it is necessary a familiarization period of approximately 10 days.
- In order to improve muscle strength and muscle mass, high frequencies (50 - 120 Hz) must be used, while low frequencies (4 - 10 Hz) just increase the cardiorespiratory fitness.
- Pulse duration must be applied in ranges of values between 100 - 500 μ s, which is shorter for small muscle groups (100 - 300 μ s) and longer for larger muscle groups (> 300 μ s).

- High duty cycles must be used in order to increase muscle mass (1:1 or 1:2) and cardiorespiratory fitness (1:1, 2:9). On the contrary, low duty cycles (1:5) must be applied to achieve strength improvements.
- The maximum voluntary contraction increases linearly with amplitude. Similarly, the increase in this last parameter does not lead to significant increases of fatigue.
- Electrical stimulation effectiveness increases when the electrodes are placed in motor points.
- Fatigue increases with frequency, while modifying pulse duration or amplitude has not a significant effect on the fatigue.
- Regarding the frequency of treatment, 2 - 3 sessions per week develop strength gains and 5 sessions per week is especially effective in order to improve cardiorespiratory fitness.

Chapter 101

SCENARIO BASED MCQS IN ORAL SURGERY

Arun Priya Srinivasan, Namdeo Prabhu and Mohammed Kassab

Oral Surgery, College of Dentistry, Jouf University, Saudi Arabia

Oral and Maxillofacial surgery is a branch of dentistry, under the broad specialty of Oral-Maxillofacial surgery and diagnostic sciences, which deals with the complex treatment of the face, jaws and the oral cavity which primarily includes the surgical management, but also involves complex medical regimes which sometimes extend in the neck region. Oral and Maxillofacial surgery also deals with the diseases and defects that affect the Head and Neck region. Numbers of sub-specialties have evolved over the period of time which can be broadly classified as Oncosurgery, Plastic Reconstructive and Orthognathic surgery, TMJ surgery and Head and Neck Trauma. Apart from the surgical treatment, Pain management and Anesthesia also forms an important part of this field of dentistry, which amounts to medical and surgical management to treat any amount of pain which also sometimes includes those of neuronal origin like Neuralgias. At the simplest methods like Dental extraction and Disimpaction of the teeth and alike tissue, along with cyst enucleation and debridement of the infection, it extends till the surgical resection of the cancer tissue and reconstruction of the missing parts of the Oral cavity and the face. A truly complex field, this branch of the dentistry is rightly addressed as a bridging link between the Surgery, Dentistry and Medicine which also encompasses the Anesthetic part.

The MCQs aid the student's and the practitioners to understand the subject effectively and to assess the knowledge acquired.

1. A 60-year-old patient suffered injuries to his lower half of face that suggested mandibular body fracture on examination. What is the most appropriate way of management of such a Patient where there is no presence of teeth?
 - A. Gunning splint**
 - B. Cap splint
 - C. Ribbon splint
 - D. All of the above

2. Long term effect of radiotherapy to oral mucosa is characterized by:
 - A. Epithelium becomes more keratinized
 - B. Sub mucosa becomes highly vascular
 - C. Break down & delayed healing, submucosa less vascular**
 - D. No sub mucosal fibrosis

3. A 20-year-old patient met with a bike accident and CT scan revealed a displaced, unfavorable fracture in the mandibular angle region. During surgery it was seen that it was a fairly difficult fracture to treat? This might be because of,
 - A. Injury to neurovascular bundle
 - B. Malocclusion secondary to injury
 - C. Distraction of fracture segments by muscle pull**
 - D. Increased density of bone in this region of mandible

4. Any trauma sustained by a jaw bone and communicating with the teeth bearing section of the alveolus should be considered as a
 - A. Simple
 - B. Open**
 - C. Greenstick
 - D. Comminuted

5. An 8-year-old child was diagnosed with fracture in twin jaws and it was further noticed it was just a single fracture line. What is the best way of treating such a fracture?
 - A. Cap splint fixation**
 - B. Intermaxillary fixation
 - C. Risdon wiring
 - D. Transosseous wiring

6. A patient came with history of sharp, lancinating pain on right side of face, not relieved by analgesics. On progressive symptoms carbamazepine was found to be effective in this patient. What is the most probable diagnosis?
 - A. Acute pulpitis.
 - B. Trigeminal neuralgia**
 - C. Acute dental abscess
 - D. Dry socket

7. Any patient being instilled with cancer chemotherapy is candidate of myelosuppression, what is the most common manifestation of this?
 - A. Anemia& thrombocytopenia**
 - B. Thrombocytosis
 - C. Leukocytosis
 - D. Lymphocytosis

8. All patients sustaining mandibular fracture will show one or all of the symptoms except:
- A. Malocclusion
 - B. Paresthesia of lower lip
 - C. Fractured ends are prevented from dislocation by masticatory muscles**
 - D. Are usually compound
9. A 47-year-old patient was suffering from severe headache and heaviness of face since 4 days. On further evaluation it was noticed that there was inflammation of most or all of the paranasal sinuses simultaneously. This condition is best described as,
- A. Pan sinusitis**
 - B. Sinusitis
 - C. Paranasal sinusitis
 - D. Parasinusitis
10. Most common culprit for Maxillary sinus infection of odontogenic origin is due to,
- A. Aerobic bacteria
 - B. Anaerobic bacteria**
 - C. Fungal
 - D. Viral
11. During a peripheral posting in a hospital it was found out that there were only basic instruments available for treatment and no means of open reduction for treating facial skeleton was available. In such a scenario all of the following are the techniques can be of help except,
- A. Risdon's wiring technique
 - B. Eyelet wiring technique
 - C. Erich's arch bar fixation
 - D. Champy miniplates osteosynthesis**
12. On doing a CT scan it was seen that mandible of a patient was badly comminuted and all fragments were grossly displaced due to muscle pull. Each of the muscle mentioned will cause displacement of the muscles except one. Which is that muscle?
- A. Lateral Pterygoid
 - B. Medial Pterygoid
 - C. Masseter
 - D. Buccinator**

13. During extraction of 16 and 17 root stump was broken and surgical procedure was instilled to remove the roots, but as soon as the root was retrieved, bubbling for the socket was seen and communication with the maxillary sinus was inferred. What is the best treatment for the accidental Oro-antral communication like this one during extraction which is around 0.5 mm in size?
- A. Buccal flap technique
 - B. Palatal flap technique
 - C. Periodic observation and follow up**
 - D. Caldwell-luc approach
14. In WINTER'S classification, white line tells us:
- A. Depth of the impacted tooth
 - B. Angulation of the impacted tooth**
 - C. Point of application for elevator
 - D. Used to classify fracture of the tooth
15. Various anatomical structures can involve in various levels of the facial trauma. In which of the following maxillary sinus is usually involved in fractures
- A. Lefort 1**
 - B. Zygomatic arch fracture
 - C. Lefort 3
 - D. Nasoethmoidal fracture
16. Which of the following methods of sterilization is not as effective as other techniques?
- A. Ethylene oxide gas
 - B. Gamma radiation
 - C. UV radiation**
 - D. Autoclaving
17. If a patient comes with a history of cardiac problem taking aspirin what will be the possible complication if you do extraction:
- A. Increases bleeding time**
 - B. Increases prothrombin time
 - C. Increases clotting time
 - D. Increases partial thrombin time
18. Cross bar elevator and winter-cryer works on mechanical principle of:
- A. Wedge
 - B. Lever
 - C. Wheel & axle**
 - D. Pulley

19. While removing an impacted wisdom tooth, if we have to do the apicoectomy of 2nd molar also, which type of incision should be given?
- A. Semilunar
 - B. Ward's
 - C. Extended ward's**
 - D. Envelop
20. Which is the most commonly used size of suture in oral cavity:
- A. 1/0
 - B. 2/0
 - C. 3/0**
 - D. 4/0
21. Which of the following can be said to have occurred if the patient develops severe pain on second postoperative day of mandibular 3rd molar disimpaction
- A. Hemorrhage
 - B. Infection
 - C. Dry socket**
 - D. Fracture of cortical plate
22. A 58-year-old man is attending surgery for extraction of his upper right canine and lateral incisor and his upper left second premolar and first molar, with insertion of an immediate partial denture. After extracting the teeth, you attempt to insert the denture but are unable to seat it. Which one of the following is the most likely cause of this problem?
- A. Bony undercut not blocked out**
 - B. Distortion of tissues by local anesthetic
 - C. Failure to use a soft lining material
 - D. Porosity introduced during processing of acrylic E Post-extraction swelling
23. A 45-year-old patient woke up with swollen face, puffiness around the eyes, and edema of the upper lip with redness and dryness. When he went to bed he had the swelling, pain or dental complaints. Examination shows several deep silicate restorations in the anterior teeth but examination is negative for caries, thermal tests, percussion, palpation, pain, and periapical area of rarefaction. The patient's temperature is normal. The day before he had a series of gastrointestinal x-rays at the local hospital and was given a clean bill of health. The condition is:
- A. Acute periapical abscess
 - B. Angioneurotic oedema**
 - C. Infectious mononucleosis
 - D. Acute maxillary sinusitis

24. A 65-year-old woman arrived for dental therapy. The answered questionnaire shows that she is suffering from severe cirrhosis. The problem that can be anticipated in the routine dental therapy is:
- A. Extreme susceptibility to pain
 - B. Tendency towards prolonged hemorrhage**
 - C. Recurring oral infection
 - D. Increased tendency to syncope
25. Patient received heavy blow to the right body of the mandible sustaining a fracture there. You should suspect a second fracture is most likely to be present in,
- A. Symphysis region
 - B. Left body of the mandible
 - C. Left sub-condylar region**
 - D. Right sub-condylar region
26. Cardiac patient came to dental office which signs and symptoms that commonly suggest Cardiac failure in him being assessed for oral surgery are,
- A. Elevated temperature and nausea
 - B. Palpitations and malaise
 - C. Ankle edema and dyspnea**
 - D. Erythema and pain
27. Patient with a cyst at the apex of an upper central incisor measuring 1 cm in diameter is visualized in radiograph and confirmed by aspiration biopsy; which method of treatment would you consider?
- A. Extraction of the central incisor and retrieving the cyst through the socket
 - B. Exteriorizing the cyst through the buccal bone and mucosa
 - C. Making a mucoperiosteal flap and removing the cyst through an opening made in the alveolar bone, followed by tooth removal
 - D. Making a mucoperiosteal flap and removing the cyst through an opening made in the alveolar bone, followed by endodontic treatment**
28. A 40 year aged patient with a persistent oro-antral fistula for a 12 weeks period following the extraction of a maxillary first permanent molar is best treated by
- A. Further review and reassurance since it will most probably heal spontaneously
 - B. Antibiotic therapy and nasal decongestants
 - C. Curettage and dressing of the defect
 - D. Excision of the fistula and surgical closure**
29. A patient complains of a stomach upset 48 hours after starting a course of antibiotic for severe pericoronitis of lower right impacted wisdom tooth, this is an example of,
- A. Type I allergic reaction
 - B. Nervous disorder
 - C. Side effect of the drug**
 - D. Type IV hypersensitivity reaction

30. A patient who is on long term aspirin therapy might show increased post-operative bleeding because aspirin inhibits:
- A. Synthesis of thromboxane A₂ and prevents platelet aggregation**
 - B. Synthesis of prostacyclin and prevents platelet aggregation
 - C. Synthesis of prostaglandin and prevents production of blood platelets
 - D. Thrombin and prevents formation of the fibrin network
31. A patient who has been taking warfarin came to oral surgery for a procedure, which of the following is not true about warfarin,
- A. INR of 3 is enough to start any extraction**
 - B. Affects extrinsic system and increases prothrombin time
 - C. Heparin can be given subcutaneously and acts rapidly
 - D. It takes at least 12 hours for Vitamin K to reverse the effects of coumarin
32. A 35 years old male patient came to oral surgery clinic with trigeminal neuralgia which of the following is NOT CHARACTERISTIC of trigeminal neuralgia?
- A. The pain usually last for few seconds up to a minute in the early stages of the disease
 - B. The pain is usually unilateral
 - C. Patient characteristically have sites on the skin that when stimulated precipitate an attack of pain
 - D. An attack of pain is usually preceded by sweating in the region of the forehead**
33. In a patient with impacted maxillary canine; by moving the X ray tube distally the canine moves distally too; where do you expect the impacted canine to be:
- A. Labially impacted
 - B. Palatally impacted**
 - C. Lingually impacted
 - D. In the maxillary sinus
34. An 8-year-old child presents with all permanent incisors erupted, but yet only three permanent first molars are erupted. Oral examination revealed a large gingival bulge in the unerupted permanent molar area. A panoramic radiograph showed the alveolar emergence of the unerupted permanent first molar crown and three fourth root developments, there are no other radiographic abnormalities. The most appropriate diagnosis and treatment plan in such situation would be:
- A. Dentigerous cyst; surgical enucleation
 - B. Idiopathic failure of eruption, surgical soft tissues exposure**
 - C. Ankylosis of the molar, removal of the first molar to allow the second one to erupt into its place.
 - D. Ankylosis of the molar, surgical soft tissues exposure and luxation of the molar

35. A young patient of 24 years came with alveolar abscess related to upper right central incisor. What is the best treatment for alveolar abscess?
- A. Endodontic treatment or extraction
 - B. Incision and drainage**
 - C. Extraction
 - D. Endodontic treatment
36. A patient 58 years old came to oral surgeon with rheumatoid arthritis the most common complication of TMJ
- A. Ankylosis**
 - B. MPDS
 - C. Internal derangement
 - D. Osteoma of condyle
37. A patient came to hospital following an accident with bilateral parasymphiseal fractures of the mandible the segment is displaced posterior under influence of
- A. Anterior belly of Digastric muscle, Geniohyoid and Mylohyoid muscles
 - B. Masseter, Lateral Pterygoid and Medial Pterygoid muscles
 - C. Buccinator, anterior and posterior belly of Digastric muscle
 - D. Geniohyoid, posterior belly of Digastric muscle and Genioglossus**
38. Patient with lupus erythematosus and on cortisone needs a surgical extraction of a tooth. What should the surgeon instruct the patient?
- A. Take half of the cortisone dose at the day of operation
 - B. Double the cortisone dose at the day of operation**
 - C. Take half of the cortisone dose day before and at the day of operation and day after
 - D. Double the cortisone dose day before and at the day of operation and day after
39. Patient presents with lateral sub-conjunctival hemorrhage, infraorbital step & diplopia on right side with inability to open mouth. It could be:
- A. Fracture subcondylar right side
 - B. Fracture zygomatic right side**
 - C. Fracture Lefort II right side
 - D. Fracture of the floor of the orbit
40. A patient presents bilateral infraorbital step, paraesthesia on left cheek region, with posterior gagging and mobility of maxillary complex at nasal bones. It indicates
- A. Bilateral fracture Zygomatic
 - B. Bilateral fracture Lefort II**
 - C. Fracture Zygomatic left side with bilateral Lefort II
 - D. Fracture bilateral sub condyle & fracture Zygomatic left side

41. A 24-year-old patient presented with sub-conjunctival hemorrhage on medial & lateral side of eye & history of bleeding from nose and mouth with disturbed occlusion. On moving the maxilla, mobility was palpable at infraorbital margins only. It can be suspected to be fracture
- A. Lefort I
 - B. Lefort II
 - C. Lefort III
 - D. Lefort II & fracture zygoma**
42. A 58-year-old male patient complained of pain on right side of tongue, inability to protrude tongue, dysphagia, increased salivation & alteration in voice, one should suspect;
- A. Carcinoma of anterior tongue
 - B. Carcinoma of posterior tongue**
 - C. Carcinoma larynx
 - D. Carcinoma epiglottis
43. A hypertension patient having café-au-lait spots, hypoplastic maxilla & signs of mental deficiency presented with soft tissue mass on buccal mucosa, this should incite surgeon to investigate for:
- A. Neurofibromatosis**
 - B. Neurilemmoma
 - C. Down syndrome
 - D. Pierre Robion syndrome
44. If after extracting a mandibular tooth, one encounters bleeding due to an underlying haemangioma, the first step in treatment would be:
- A. Carotid artery ligation
 - B. Inferior alveolar artery ligation
 - C. Replacing the tooth in the socket**
 - D. Pressure packing
45. A 12-year-old patient had episodes of haemarthrosis but characteristically petechiae & ecchymosis were not seen. His BT & platelet count was normal. It is hematological picture of:
- A. Hemophilia A**
 - B. Thrombocytopenic purpura
 - C. von Willebrand's disease
 - D. Scurvy
46. A 12-year-old patient of thrombocytopenic purpura has to undergo minor oral surgery procedure; he should first be given:
- A. Packed red cells to improve oxygen carrying capacity of blood
 - B. Fresh frozen plasma to provide coagulation factors
 - C. Platelet-rich plasma to allow normal clotting**
 - D. None of above since his BT/CT should be normal

47. Following roadside accident, a patient presented with bleeding from ear and impaired hearing with sign of head injury, there could be a fracture of:
- A. Anterior cranial fossa
 - B. Middle cranial fossa**
 - C. Posterior cranial fossa
 - D. Mandibular fracture
48. A 15-Year-old otherwise healthy female patient presents at 1pm with a large, firm, brawny submandibular swelling on the right side. The patient has severe trismus, pyrexia and radiographs show a grossly carious lower right 6, the patient has some dysphagia but the tongue is not elevated, which of the following is/are indicated?
- A. Start antibiotics intramuscularly and drain the abscess under local anesthesia following admission a ward and medical care
 - B. Start antibiotics intramuscularly and drain the abscess under general anesthesia following admission a ward and medical care**
 - C. Aspirate swelling and send to culture and sensitivity test to begin antibiotic therapy
 - D. Give corticosteroids
49. A 29-year old patient taking 60mg hydrocortisone for the last one month, requires periodontal surgery:
- A. It should not be carried out.
 - B. The dose should be halved and then surgery carried out.
 - C. The dose should be doubled and then surgery performed
 - D. NO change in dose should be made and surgery should be carried out**
50. Patient with iron deficiency anemia came for extraction of impacted wisdom tooth. Which of the following would be a contraindication for such a procedure?
- A. HB = 7 mg/dl**
 - B. HB = 11 mg/dl
 - C. HB = 12 mg/dl
 - D. HB = 13 mg/dl
51. Healthy pregnant woman came for extraction of lower wisdom tooth and she went into syncope. Which of the following is the most common cause?
- A. Hypotension**
 - B. Hypertension
 - C. High blood sugar
 - D. Low blood sugar
52. A 60-year-old patient suffered injuries to his lower half of face that suggested mandibular body fracture on examination. What is the most appropriate way of management of such a patient where there is no presence of teeth?
- A. Gunning splint**
 - B. Cap splint
 - C. Ribbon splint
 - D. All of the above

53. Long term effect of radiotherapy to oral mucosa is characterized by:
- A. Epithelium becomes more keratinized
 - B. Sub mucosa becomes highly vascular
 - C. Break down & delayed healing, submucosa less vascular**
 - D. No sub mucosal fibrosis
54. Trauma to lower third of face is characterized by all of the following except.
- A. Fractures of the mandible are common at the angle of the mandible
 - B. Fractures of the mandible are affected by the muscle pull
 - C. Fractures of the mandible are usually characterized by sublingual hematoma
 - D. CSF Rhinorrhea is a common finding**
55. A decision was made to treat a mandibular body fracture with closed reduction using ivy-eyelet wiring technique. Such a fracture mandible should be immobilized for an average of
- A. 3 weeks
 - B. 6 weeks
 - C. 9 weeks
 - D. 12 weeks**
56. In a worldwide consideration which part of the mandible can be considered to be suffering traumatic fractures the most?
- A. Body
 - B. Angle
 - C. Symphysis
 - D. Condyle**
57. A six-year-old child fell from a height and it was noticed on CT scan that one of the cortices of his mandible was fractured while other one was almost intact. What kind of fracture can be said to have occurred in him?
- A. Displaced fracture
 - B. Telescopic fracture
 - C. Greenstick fracture**
 - D. Overlapping fracture
58. An 8-year-old child fell on his chin while playing football and mid-symphysis fracture of lower jaw was noticed. What is the treatment of choice in such a patient?
- A. Intermaxillary fixation
 - B. Cap splint with circumferential wiring**
 - C. Open reduction
 - D. No treatment indicated

59. Submandibular gland is known to open in floor of the mouth by various openings but one of them forms a major duct to carry out secretions, which one of the following is that?
- A. Bartholin's duct**
 - B. Minor salivary gland's duct
 - C. Stenson's duct
 - D. Wharton's duct
60. Which of the following complication may result from injury to auriculotemporal nerve during removal of parotid tumor is:
- A. Facial palsy
 - B. Gustatory sweating**
 - C. Oro lingual paresthesia
 - D. Anorexia
61. Duct for the parotid gland opens commonly in which region
- A. Upper 2nd molar**
 - B. Upper 3rd molar
 - C. Lower 2nd molar
 - D. Lower 3rd molar
62. Cross bar elevator which works on the wheel and axle principle has a mechanical advantage of
- A. 1.5 times the force applied
 - B. 3 times the force applied
 - C. 4.5 times the force applied**
 - D. 5.5 times the force applied
63. Which is the most preferred size of suture for skin sutures of face:
- A. 1/0
 - B. 2/0
 - C. 3/0
 - D. 4/0**
64. Person with known history of diabetes mellitus has been on medications for past 10 years and needs a surgical extraction of 38. What is the best way of managing such a patient on the day of surgery?
- A. Double the dose of Insulin
 - B. Double the quantity of breakfast
 - C. Usual dose of insulin and Breakfast**
 - D. To not take insulin and come nil per oral

65. A 23-year-old male patient started having epileptic attack following overdose administration of local anesthesia and was not subsiding. The agent of choice to reverse status epilepticus induced by local anesthetic overdose is?
- A. Phenobarbital
 - B. Epinephrine
 - C. Oxygen
 - D. Diazepam**
66. A 40-year-old patient with severe maxillofacial injuries presented to the emergency in an unconscious state, he has to be
- A. Immediately treated for maxillofacial injuries
 - B. Immediately Glasgow coma scale should be assessed
 - C. Immediately airway should be secured**
 - D. Immediately examine for any associated fractures
67. A young female patient presented with a history of trauma to the face following a road traffic accident. On examination flattening of cheek on the left side was observed suggesting zygomatic arch fracture. The suggested radiograph will be
- A. Occlusal view
 - B. Facial Profile Survey
 - C. Reverse - Towne Projection
 - D. Submentovertex Projection**
68. A patient with continuity defect of mandible due to segmental resection of mandible is reconstructed using anterior iliac crest graft. This graft is an example for
- A. Autogenous Corticocancellous bone graft**
 - B. Autogenous Cancellous bone graft
 - C. Xenograft
 - D. Alloplastic bone graft
69. A 60-year-old patient with mandibular fracture was admitted post operatively in the ICU following open reduction and internal fixation. He suffered from nosocomial pneumonia. The most commonly involved organisms are
- A. Gram positive organisms
 - B. Gram negative organisms**
 - C. Mycoplasma
 - D. Virus infections
70. A female patient with a huge swelling on the face is diagnosed with buccal space infection. The method of treatment is
- A. William's method of abscess drainage
 - B. Hilton's method of abscess drainage**
 - C. Hilton's method of enucleation
 - D. William's method of decompression

71. A child was diagnosed with cleft of lip and palate upon birth, the initial step in management is
- A. Nasoalveolar moulding**
 - B. Surgery for cleft lip
 - C. Surgery for cleft palate
 - D. No treatment till adulthood
72. A patient with deep soft tissue laceration on the right mandibular region of the face associated with displaced parasymphysis of the right side walked into the emergency.
- A. The soft tissue is closed with layered sutures, and the patient is posted for fracture reduction the next day.
 - B. The soft tissue debridement is done and stay sutures are placed. The patient is posted for fracture reduction the next day.**
 - C. The patient is posted for surgery immediately for both soft and hard tissue management.
 - D. The patient is treated with closed reduction for parasymphysis fracture and stay sutures are placed for soft tissue.
73. A 50-year-old patient with history of chronic alcoholism requires multiple extractions. Which of the following conditions will he be more prone for?
- A. Increased PTT**
 - B. Increased blood sugar levels
 - C. Decreased PTT
 - D. Decreased INR
74. A 30-year-old patient had a severe cardiac arrest on the dental chair. After how much time of total oxygen obstruction to brain, permanent neurologic damage can occur?
- A. 1 min
 - B. 2mins
 - C. 3mins**
 - D. 4mins
75. A patient with mild gnawing pain radiating around the right TMJ reported to our unit requesting extraction of upper and lower third molars of the right side. On examination, the muscles on the affected side were tender and the pain was radiating. Intraoral examination revealed fully erupted, non-carious upper and lower third molars in occlusion. The most probable diagnosis is
- A. MPDS**
 - B. Pericoronitis
 - C. TMJ Dislocation
 - D. Periapical disease of lower third molar

76. A 25-year-old patient with upper canine impaction gave a radiographic picture of canine placed horizontally in the palate. How do we classify this position?
- A. WHO Class I**
 - B. WHO Class II
 - C. WHO Class III
 - D. WHO Class IV
77. A 30-year-old patient had a hard swelling on the palate in the midline measuring around 0.5 cm to 1 cm. The swelling was painless on palpation and non-mobile. What is the most probable diagnosis?
- A. Lipoma
 - B. Torus palatinus**
 - C. Fibroma
 - D. Osteosarcoma
78. A 40-year-old female patient presented with a swelling on the right side of the forehead since many years, and is gradually growing in size. On examination, it was well circumscribed, soft, and not attached to the underlying structure. Slip sign was positive. What is your diagnosis and management?
- A. Sebaceous cyst, Aspiration of the contents
 - B. Infected follicle, Antibiotics
 - C. Lipoma, excision**
 - D. Hyperplastic frontalis muscle shaving
79. An 18-year-old female patient was diagnosed with a radicular cyst extending from left canine to right canine of the mandible. The preferred treatment is
- A. Segmental resection of mandible
 - B. Marsupialization**
 - C. Electrocautery
 - D. Cryotherapy
80. A 60-year-old female patient, who was on long term bisphosphonate therapy for multiple myeloma, underwent extraction of 34 and 35. Postoperatively the mandibular bone was exposed and painful, with halitosis, swelling, and orocutaneous fistula. This condition is
- A. Dry socket
 - B. Osteonecrosis**
 - C. Osteoradionecrosis
 - D. Osteomyelitis
81. A 34-year-old patient presented with nasal bone fracture and deviated nasal septum with a history of trauma during boxing. It can be reduced using
- A. Ashley's and Walsham's forceps**
 - B. Ashley's and Rowe's disimpaction forceps
 - C. Walsham's and Rowe's disimpaction forceps
 - D. Index finger and thumb

82. A 40-year-old male patient with multiple facial fractures (PAN FACIAL TRAUMA) reported to the emergency unit with respiratory distress. The best way to secure airway is
- A. Blind nasal intubation
 - B. Oral airway
 - C. Emergency tracheostomy**
 - D. Mouth to mouth breathing
83. A 21-year-old female patient complained of large swelling on the right side of the face extending to neck, following the access opening of right lower second molar the previous day. Most likely she developed
- A. Abscess of submandibular space
 - B. Cellulitis**
 - C. Chemical burn
 - D. Allergic condition
84. A 25-year-old female patient presented with drooping of upper eyelid, drooling of saliva and inability to close the eye on the left side of the face following parotidectomy of the left side. The reason could be
- A. Injury to facial nerve**
 - B. Injury to trigeminal nerve
 - C. Injury to parotid gland
 - D. Injury to optic nerve
85. Following road traffic accident, a 50-year male patient presented with disturbed occlusion, ecchymosis in the greater palatine foramen region, ecchymosis in the buccal sulcus and mild mobility of the maxillary segment. And no tenderness over the nasal bridge or frontozygomatic suture region. The clinical diagnosis will be
- A. Dentoalveolar fracture
 - B. Lefort I fracture**
 - C. Lefort II fracture
 - D. Lefort III fracture
86. A 35-year-old female patient required extraction of left upper molars, but since she presented with exophthalmos, tremors and increased blood pressure the operating surgeon suspected
- A. Hypertension
 - B. Hyperthyroidism**
 - C. Hypothyroidism
 - D. Adrenal crisis

87. A 45-year-old male patient was ambulated to the emergency in a semiconscious state. He was diagnosed with mandibular, zygomatic and femoral fracture. Which of the fracture should be addressed first?
- A. Mandibular fracture
 - B. Zygomatic fracture
 - C. Femoral fracture**
 - D. Treatment should be postponed till he gains consciousness
88. A female with maxillofacial injuries was ambulated to the emergency following road traffic accident. She had feeble pulse, fall in blood pressure and tachycardia indicating hypovolemia. The circulatory volume should be immediately compensated with
- A. Blood of the same group
 - B. Crystalloids**
 - C. Colloids
 - D. Universal blood group
89. A patient with bilateral parasymphysis fracture of the mandible presenting with respiratory distress. The most likely cause will be
- A. Blood clot in the mouth
 - B. Tongue falls back and obstructs the airway**
 - C. Soft palate obstructs the airway
 - D. Hyoid bone is compressed
90. In a patient with bilateral parasymphysis fracture of the mandible presenting with respiratory distress the immediate measure taken to maintain airway is
- A. Pull the tongue with suture or towel clip**
 - B. Emergency tracheostomy
 - C. Emergency cricothyroidectomy
 - D. Jaw thrust method
91. While extracting a maxillary premolar the buccal root of the tooth got fractured, while trying to retrieve the root, it vanished from the socket. On radiograph the maxillary sinus was clear. Which is the next possible location for the root to escape
- A. Palatal space
 - B. Buccal space**
 - C. Nasal cavity
 - D. Orbital cavity
92. A young male patient was diagnosed with comminuted fracture of mandible. The ideal method of fixation is
- A. 2.5 mm plate
 - B. 1.5 mm plate
 - C. Dynamic compression plates with eccentric holes
 - D. Reconstruction plates with central holes**

93. A young female patient complained of painless swelling on the right side of the mandible which gradually increased in size. Histology revealed abnormal fibrous connective proliferation in which new non-maturing bone is seen, replacing the normal bone. The treatment is
- A. Enucleation of the lesion
 - B. Bone shaving**
 - C. Mandibulectomy
 - D. Radiation
94. A patient with suspected central giant cell granuloma was advised to check his levels of parathyroid hormone to rule out
- A. Primary hyperparathyroidism**
 - B. Primary hypoparathyroidism
 - C. Primary hyperthyroidism
 - D. Primary hypothyroidism
95. Which of the following is false?
- A. Gingival and palatal cyst of newborn is derived from dental lamina
 - B. Epstein's pearl is found along the mid palatine suture
 - C. Bohn's nodules are found along the mid palatine suture
 - D. Palatal cyst of newborn persists into adult life**
96. Which of the following glands is both endocrine and exocrine in nature?
- A. Pancreas**
 - B. Thyroid gland
 - C. Sweat gland
 - D. Pituitary gland
97. Which of the following GA agent is contraindicated in severe coronary artery disease
- A. Ketamine**
 - B. Fentanyl
 - C. Thiopentanyl
 - D. Xylocaine
98. Glenoid fossa is found in:
- A. Orbital cavity
 - B. Nasal cavity
 - C. Middle cranial fossa
 - D. Temporal bone**

99. After you inject LA for maxillary 2nd molar, the patient's face becomes colorless with an extraoral swelling. Its due to:
- A. Facial artery
 - B. Plexus of vein**
 - C. Posterior alveolar nerve
 - D. Maxillary artery
100. Patient reports to the clinic with the history multiple lesions of the Head and neck manifested as nevi with is the most probable diagnosis?
- A. Peterson Kelly syndrome
 - B. vander Woude syndrome
 - C. Eagle syndrome
 - D. Albright syndrome**
101. All the following are examples of diseases causing aplastic anemia, EXCEPT:
- A. Hepatitis
 - B. Pregnancy
 - C. Cold hemoglobinuria**
 - D. PNH
102. A 5-year-old child came to the set up with an avulsed tooth. What is the most important factor that affects reimplantation of avulsed tooth
- A. Time since the avulsion**
 - B. Skill of dentist
 - C. Contaminated roots
 - D. Patient age
103. An increase in shear stress in a blood vessel results in which of the following changes?
- A. Decreased endothelin production
 - B. Increased nitric oxide**
 - C. Increased rennin production
 - D. Decreased prostacyclin production
104. Which of the following patterns is the characteristic of the response to nerve stimulation produced by a depolarizing neuromuscular agent
- A. A Lack of fade in response to train of four**
 - B. Increase in post-tetanic stimulation
 - C. Tetanus is associated with fade in muscle response
 - D. Fourth twitch of TOF disappears with 60-70% receptor occupancy
105. Drainage of tip of the tongue:
- A. Sub lingual lymph nodes
 - B. Submental lymph nodes**
 - C. Submandibular lymph nodes
 - D. Parotid lymph nodes

106. Base of the flap should be wide for:
- A. Healing
 - B. For better suture placement
 - C. Better blood supply to the wound.**
 - D. Nothing relevant

Chapter 102

THE ROLE OF SURGERY IN THE TREATMENT OF OSAS

***F. Lorusso^{*}, MD, A. Battaglia, MD,
A. Mistretta, MD and S. Gallina***

Unit of Otolaryngology, Department of Experimental Biomedicine and
Clinical Neurosciences, Polyclinic University Hospital “Paolo Giaccone”,
University of Palermo, Via del Vespro, Palermo, Italy

ABSTRACT

The American Academy of Sleep Medicine [1] and the American Academy of Otolaryngology–Head and Neck Surgery [2] recommend surgery as an option for the treatment of OSAS, when non-invasive treatments such as CPAP or oral appliances have not been successful or are not tolerated. Surgical treatment is more effective when there is an evident anatomical deformity that can be corrected to alleviate the respiratory obstruction.

According to the American Sleep Apnea Association, a gradual and logical approach must be taken into account when a patient seeks a surgical solution, and it is a fundamental requirement that the patient find a surgeon who understands both the pathophysiology of sleep apnea and anatomy of the upper airways (UA) to guarantee the best chances of success [3].

The surgical options aim to solve the obstructive problem according to two ways, the first is the reduction of the content, and then acts through the volumetric reduction of soft tissues at the level of UA, most often at the level of palate, uvula, tonsils, adenoids and tongue. The second option aims at enlarging the container, and therefore on more complex interventions to adapt the bony structures of the skull.

Surgical interventions can be schematically divided into nasal surgery, oropharyngeal surgery, hypopharyngeal surgery, laryngeal surgery, multilevel surgery and upper airway by-pass.

The soft palate in the snore-surgery is the anatomical site on which most of the attention has always been concentrated since it is responsible for most of the phenomena of snoring and most of the obstructive ones and has undergone the greatest innovations.

^{*} Corresponding Author’s Email: dott.francescolorusso@gmail.com.

The rationale for palatal surgery is to reduce volume and stiffen a structure that vibrating with the passage of air causes snoring and collapsing causes an obstruction of the UA.

In general, interventions on the palate can be broadly divided into two groups, the first is represented by interventions that have the aim of reduce snoring, and in this case are less invasive surgeries, as the goal is that of stiffening the palate and reducing the excess mucosa that vibrating causes snoring.

The second group consists of interventions that have the aim of reducing above the snoring especially the apnoic episodes, so they are interventions that have a greater invasiveness, since they must stiffen and reconstitute the functionality of a segment of the UA.

In this context, in the last few years great importance has been placed in the surgeon of the oropharynx side wall starting from the Cahali techniques [4], followed by the Expansion Sphincter Pharyngoplasty by Pang and Woodson [5] up to the innovative techniques such as the Barbed Reposition Pharyngoplasty of Vicini and Mantovani [6].

SURGICAL TREATMENT

The American Academy of Sleep Medicine [1] and the American Academy of Otolaryngology–Head and Neck Surgery [2] recommend surgery as an option for the treatment of OSAS, when non-invasive treatments such as CPAP or oral appliances have not been successful or are not tolerated. Surgical treatment is more effective when there is an evident anatomical deformity that can be corrected to alleviate the respiratory obstruction.

According to the American Sleep Apnea Association, a gradual and logical approach must be taken into account when a patient seeks a surgical solution, and it is a fundamental requirement that the patient find a surgeon who understands both the pathophysiology of sleep apnea and anatomy of the upper airways (UA) to guarantee the best chances of success [3].

The surgical options aim to solve the obstructive problem according to two ways, the first is the reduction of the content, and then acts through the volumetric reduction of soft tissues at the level of UA, most often at the level of palate, uvula, tonsils, adenoids and tongue. The second option aims at enlarging the container, and therefore on more complex interventions to adapt the bony structures of the skull.

Fundamental assumptions are:

- the patient must be highly motivated and must express the desire to carry out the treatment,
- treatment should not damage the patient and after any treatment nasal ventilatory therapy should remain possible,
- surgical treatment must be planned according to the patient's specific anatomical characteristics and the severity of the syndrome.
- As with all other treatment modalities, there is no surgical intervention that can guarantee a certainty of a stable result over time.
- More serious is the OHSAS, more complex and challenging it is the effective intervention.

- In any case we will try to opt for the minimum effective solution able to manage the severity of the complained disorder.

Nasal surgery

- Septoplasty
- Functional rhinoplasty, nasal valve surgery
- Turbinate surgery
- Adenoidectomy
- Nasal polypectomy
- Endoscopic procedure

Oropharyngeal surgery

- Tonsillectomy
- Palatal surgery (uvulectomy and pharyngoplasty)
- Minimally invasive surgery (RF, pillar, sclerotherapy)

Hypopharyngeal surgery

- Hyoid suspension
- Lingual surgery (tongue reductions, glossectomies and TORS)
- Advancement of genioglossus
- Mandibular advancement

Laryngeal surgery

- Epiglottectomy
- Supraglottoplasty

UA by-pass

- Tracheostomy

Global procedures

- Bi-maxillary advancement
- Multilevel surgery
- Bariatric surgery

NASAL SURGERY

The relationship between sleep disorder breathing (SDB) and nasal function is complex, in fact the nose is not only an obstructive site, but it also has considerable influence on the most downstream sites because a difficult nasal breathing creates an increase in negative pressure at the level of the pharyngeal tract it is more collapsible. If the obstruction is such that it does not allow an adequate air flow, it causes the necessary passage to oral breathing, with consequent worsening of the obstruction linked to the lingual and hypopharyngeal component.

There are many interventions aimed at improving nasal breathing, but none of these is considered alone as OSAS surgery, as the improvement of nasal breathing can also drastically reduce the signs and symptoms associated with SDB, but in most cases the benefit is partial.

- Septoplasty
- Decongestion of inferior turbinates
- Turbinoplasty
- Polypectomy or endoscopic surgery
- Functional rhinoplasty, nasal valve surgery

The results on snoring are often controversial and are also difficult to interpret because often there is an improvement of the noise, since they reduce the constrictions and the vortical flows at the nasal level responsible for the nasal snoring. But in other cases there may be a worsening of the symptomatology due to the greater vibration of the soft tissues of the most downstream sites linked to the greater air flow established thanks to the surgery.

Usually the improvement of nasal breathing is associated with an improvement in the quality of sleep and daytime vigilance. The results on the OSAS are however partial and aleatory.

Only Rubin and coll. [7] in their study achieved a significant improvement in OSAS severity only with nasal surgery, while remaining far from the parameters of surgical success. In subjects with mild OSAS, nasal tamponade is usually not a problem. But in patients with moderate to severe OSAS, nasal tamponade can precipitate respiratory failure in post-surgery. Therefore, in these cases it would be appropriate to use medications that allow nasal breathing through appropriate channels. The most risky period is represented by the first 6 hours post-surgery [7], therefore in this period the patient should be constantly monitored. In subjects with severe OSAS who have already undergone CPAP therapy and who must necessarily receive post-operative nasal tamponade, it is recommended to resume post-operative CPAP therapy immediately, either with a facial mask or an oral mask.

The importance of nasal surgery in improving nCPAP compliance should not be forgotten [8].

Friedman et al. [9] in a group of patients undergoing septoplasty and lower turbinoplasty reported a reduction in CPAP pressure required to resolve OSAS from 9.3 mbar to 6.7 mbar. Dorn and coll. [10] showed a reduction in CPAP of 3.2 mbar, 6 weeks after nasal surgery.

Rhinopharyngeal Surgery

If an obstacle is detected, its ablation is indicated here, but assumptions and expectations are similar to those of nasal surgery. The most frequent causes are adenoid hypertrophy and rarely antrocoanal polyps in children, while in adults there are rarely obstructions at this level. Should this occur, attention must be paid to the risks of scarring stenosis in case of a contemporary adenoidectomy to palatal surgery, in fact it is not recommended by many authors to make it in a single time.

In children, adenoid hypertrophy contributes to the determinism of childhood SDB. But adenoidectomy is not sufficient to solve the OSAS problem, but together with tonsillectomy it

is considered the primary therapy for the resolution of infant SDB. [11] Adenoidectomy is to be considered only in simple snoring in fact it is known in children a strong relationship between the adenoid dimension and snoring [12, 13]. Nieminen et al. [14] in a prospective non-randomized controlled trial evaluated with PSG a group of children subjected to adenoidectomy before and after surgery, 73% of these did not resolve the obstructive problem or symptoms started after adenoidectomy, probably due to compensatory tonsil hypertrophy.

Oropharyngeal Surgery

The oropharynx is the anatomical site with the most important role in the ronco-surgery as it is located at the carrefour between the oral and nasal respiratory tract, and it is mostly at this level that due to the considerable presence of loose structures there is the greatest influence on the obstruction of the UA.

Therefore, the objectives of the ronco-surgery at this level are two [15]:

1. Reduction/abolition of vibrating tissue responsible for snoring;
2. Reduction/abolition of the obstructing tissue responsible for RERAs, hypopneas and apnea.

Tonsil Surgery

Child's Tonsillar Ronco-Surgery

Tonsillar hypertrophy is the main cause of OSAS and snoring in the pediatric population [16-18]. The age of less than three years, neurological and maxillofacial comorbidity are to be assessed with care and caution for an increased post-operative risk and for a greater share of failures. The opportunity for post-operative monitoring in pediatric intensive care units should be considered in this group of patients.

Various techniques have been developed that can be basically divided into two basic types of intervention:

- *Tonsillotomy or tonsillar volumetric reduction:* which consists in reducing the volume of the tonsils, with preservation of their capsule, which can be performed with various instruments such as coblator, microdebrider, radiofrequency. This technique appears to be burdened with a lower risk of post-operative bleeding [19]. But it presents the risk of recurrence of hypertrophy.
- *Tonsillectomy:* which consists in the complete removal of the tonsil with its capsule, it can be performed with cold techniques or with hot techniques [20]. These latter techniques are burdened from a slightly higher risk of post-operative late hemorrhage 2-4%, compared to 1-2% of cold techniques [21].

The almost total disappearance of night snoring after adenotonsillectomy in children is widely known, but there are only a few studies to prove it.

The work of Hultcranz et al. Is interesting in this regard [22] that in a randomized study compared the effectiveness on tonsillectomy and tonsillotomy snoring after one year, showing

a 9.5% recurrence of snoring in the group of patients undergoing tonsillotomy, suggesting a possible relapse hypertrophy.

Adenotonsillectomy is considered the first line treatment in the treatment of pediatric OSAS [2, 15, 24-27].

Brietzke [28] in his meta-analysis has shown how obesity is a fundamental factor in the determinism of the presence of post-surgical OSAS residue. Finding an AHI > 5 sleep events/hour in 59% of obese children subjected to adenotonsillectomy. And highlighting as predisposing factors in the maintenance of a post-operative high AHI age > 7 aa, the presence of asthma and a severe preoperative OSAS, in all these cases the child must undergo post-operative polysomnography, to evaluate the possible presence of residual OSAS.

In an attempt to reduce post-operative pain, various devices have been developed, which in most cases aim to achieve the simplicity of a tonsillectomy with hot instruments while maintaining contained temperatures of use. From this point of view we conducted a comparative study between tonsillectomy for cold dissection and tonsillectomy with Molecular Quantum Resonance, results showed a saving in surgical time and a significant reduction in intra-operative bleeding, although not having significant results with regard to post-operative pain that was substantially overlapping [20].

Adult's Tonsillar Surgery

The hypertrophic palatine tonsil is a significant obstacle at the VAS level, easily eliminated with relatively rudimentary surgery, but usually this is not sufficient to completely solve the snoring and OSAS problem. As evidenced by Tzifa and coll. [29] tonsillectomy in children does not reduce the risk of becoming snoring adults. Rarely in the surgical treatment of snoring and OSAS is it limited only to tonsillectomy, but when this procedure is performed within a multisite procedure the contribution of tonsillar time to overall success appears to be relevant. This is also due to the fact that an important tonsillar hypertrophy is rare in the adult subject, but when this happens the tonsillectomy has a success rate similar to that of the pediatric age.

Tonsillar Volumetric Reduction Radio-Frequencies

The principle consists in the submucosal application of low frequency radio waves. It is used as an interstitial treatment, with an electrode that is inserted into the soft tissue of the tonsil creating a thermal lesion that causes necrosis and is followed by successive cicarizal processes. As a consequence, the soft tissue shrinks and stiffens. [19, 30].

Palatal Surgery

The soft palate in otolaryngology surgery is the anatomical site on which most of the attention has always been concentrated since it is responsible for most of the snoring phenomena and a good part of the obstructive ones.

The rationale of palatal surgery is to reduce volume and stiffen a structure that vibrates with the passage of air causing snoring and collapsing causes an obstruction of the UA.

Generally, interventions on the palate can be broadly divided into two groups, the first is represented by treatments that aim to reduce snoring, and in this case they are less invasive surgical interventions, as the goal is that of stiffening the palate and reducing the excess mucosa that vibrates, causing snoring. The second group is made up of the treatments that

aim to reduce the apnoic episodes above snoring, therefore they are surgical interventions that have a greater invasiveness, since they must stiffen and rebuild the functionality of a segment of the UA.

- Treatment of Snoring

Uvulectomy

In literature there are few results regarding the uvulectomy as a single surgical treatment for the treatment of snoring. It is a very painful procedure and is not recommended, except for removing the exuberant mucosa, especially if you are going to resect the muscular component of the uvula. As demonstrated by Mortimore [31], mere resection of the uvula increases oral bleeding in patients undergoing CPAP.

Radiofrequency (RF) Snoreplasty

In 1995 Whinney et al. suggested a procedure considered to be a precursor to soft palatal RF, using diathermocoagulation of the palatal muscles by infixion [23]. The use of RF has made it possible to considerably reduce thermal damage. The procedure is usually performed under local anesthesia with the patient in a sitting position. But it can also be associated with other nasal procedures or tonsillectomy and is therefore performed in the context of a general anesthesia.

There are numerous studies on the effectiveness of RF on snoring with an average improvement of about 82.4%. The most frequent complications are burn, erosion and ulceration of the lining mucosa. This phenomenon, however, besides causing a greater post-operative pain, usually does not affect the final result since, if the lesion is only on the ventral side of the palate, it creates a greater scarring reaction that makes the palate more rigid. On the other hand, excessively deep thermal lesions that cause damage to the mucous membrane of the dorsal side of the palate are to be avoided, causing an alteration of the healing dynamics.

Certainly effective on simple snoring, it can also be effective in mild OSAS, both as a single technique on the palate and in a minimally invasive multilevel surgery.

Injection Snoreplasty

The rationale is similar to that of the RF, only that instead of the thermal stimulus, sclerosing substances are used to induce the formation of scars on the palate. Introduced for the first time in 2001 by Brietzke [33], initially using a 3% solution of sodium tetradecyl sulfate (STS). Provided after local anesthesia at sub-mucosal level, and within a few weeks the mucosa undergoes healing. Transient improvement in snoring has been reported.

Palatal Implants

They consist of small polyethylene splints (PET) similar to that used for vascular endoprostheses or gastric meshes. Three of these are applied under local anesthesia thanks to a special applicator in the context of the palatal musculature, stimulating a fibrotic reaction that creates a capsule around the implant with the aim of stiffening the palate reducing its vibration.

The technique has been virtually abandoned in the light of poor clinical results encountered and of the rare, but still detected episodes of implant expulsion with a percentage from 0 to 25% [34].

Velo-Uvulo-Pharyngeal Lift (VUPL)

In 2008 Hur [35] proposed a technique of snoreplasty based on the stiffening of the redundant soft tissues of the soft palate through the trans-mucosa introduction of permanent sutures through the fibro-muscular plane of the palate. This study achieved poor results on the OSAS, but highlighted the perfect tolerability of these sutures, already widely used in plastic surgery, at the palatal level, allowing to obtain the desired modifications in the fibro-muscular tissues surrounded by the sutures. In 2012 Mantovani and coll. [36], have developed a new palatal lifting technique using non-resorbable sutures, the so-called “Roman blinds” technique. This has the aim not only to make the veil-uvular complex rise and stiffen, but also making it advance also widens the mesopharyngeal space to eliminate the noisy vibrations or occlusions. The technique involves the use of non-absorbable 2-0 sutures that are anchored with different passages to three bony structures (the two pterygoid hamuli, and the posterior nasal spine), through a small mucosal incision and then in a loop inside the palatopharyngeal fibro-muscular tissues. The side effects of the technique were limited to post-operative pain that disappears rapidly within a few days. Subsequently the technique has been further implemented [37] with the use of barbed wires (QUill ® Knotless Tissue Closure Device, Angiotech Pharmaceutical inc., Vancouver, CA), normally used in vascular surgery, which do not require knots, as they are self-locking and allow you to get new geometries.

- Treatment of Apnea

The first plastic coded intervention of the soft palate was described for the first time by Ikematsu in 1963, since then numerous interventions have been proposed that aim to reduce the excess components of the soft palate tissue, without compromising the swallowing and phonatory functions. In fact the palatoglossus muscle (anterior palatal pillar) contains within it neuro-muscular spindles, playing an important role in swallowing and therefore must be preserved together with the muscle of the uvula.

While the glossopharyngeal muscle (posterior palatal pillar) has no neuro-muscular spindles, therefore, it can be partially dissected without hindering swallowing or the possibility of a future nasal ventilatory therapy (nCPAP). In fact, an excessive resection of the palatal musculature creates serious difficulties in the application of nCPAP due to oral venting. A fundamental prerequisite of palatal surgery is the implementation of techniques that make it possible to maintain CPAP in any case as a therapeutic alternative in the event of failure.

Indications and contraindications are similar for all palatal interventions to reduce apnea. Indications for exclusive palatal intervention:

- Hypertrophic and elongated uvula (dolico-mega-uvula)
- Palatine Ptosis
- Thick palate
- Tonsillar hypertrophy

- Restricted oropharyngeal isthmus
- Plication of the pharyngeal walls
- BMI <30
- AHI <20 or simple snoring

Absolute contraindications of palatal surgery

- Cleft palate
- Short palate
- Insufficient oral opening, interdental distance <3 cm (small operating field)
- Chronic cardiac or pulmonary disorders
- Neurological or psychiatric disorders requiring pharmacological treatment
- High anesthetic risk
- Alcoholism
- Sedative abuse
- Skull facial anomalies

Contraindications to treatment with palatal surgery only

- Obesity: generally represents a negative selection criterion. But only palatal intervention with BMI > 30 is contraindicated
- severe OSAS, AHI > 30 also 20 according to some authors
- Retrognathia or micrognathia (usually lingual back obstruction)
- Severe occlusal or temporomandibular joint dysfunction (oral opening <3cm)
- High distance between the hyoid and lower edge of the jaw

Relative contraindications of palatal surgery

- Professional use of the voice
- Wind instrument players
- Scuba diving activities (possible problems of tubal compensation)
- Professional use of taste

Uvulo Palato Pharyngoplasty (UPP or UP3)

The original technique was first described by Ikematsu in 1963, since then numerous variants have been proposed, as long as UPPP is to be considered as a group of procedures.

The first UPPs included a very aggressive resection of the soft palate with frequent complications such as velo-farinea insufficiency 24% [38], 4% nasopharyngeal stenosis [39] and frequent failure to use nCPAP due to oral venting [40]. Therefore these techniques have been globally abandoned.

UPP is effective in the resolution of snoring of velar origin.

Hassid et al. [41] have recently described a decrease in success rates with increasing follow-up periods.

A polysomnographic follow-up is recommended after 1-3 aa. From the data it is clear that the effectiveness of UPPP decreases over the years. Using the Sher success criteria as a parameter (AHI reduction > 50% and values <20) [42], a long-term success rate of 49.5% is achieved.

According to the AASM in patients with moderate-severe OSAS, UPPP with or without tonsillectomy does not allow a normalization of the AHI therefore should be proposed only after a manifest refusal of treatment with CPAP or oral appliances [43].

The effectiveness of the surgery is not proportional to the size of the resection while the side effects and risks are directly proportional to the size of the resection [15].

Mortimore [31] has shown that an aggressive resection of the velar muscles during UPPP does not allow the application of nCPAP at pressures greater than 13 cm of H₂O.

Excessive aggression on the side walls and post-operative infections are the main cause of nasopharyngeal strictures.

Uvulo-Palatal Flaps

Palatal flaps are generally an interesting alternative to UPPP and are indicated for primary snoring and mild to moderate OSAS. Post-operative pain is less than UP3. The operation is always preceded by tonsillectomy, in the case of tonsillectomized patients unlike UPPP the scar tissue should not be removed to highlight the pharyngeal palate muscle that should not be dissected here. The tip of the uvula must be pulled down and an incision is made about 2 cm away from the contact point represented by the junction between the hard palate and the soft palate. At this point part of the redundant mucosa is removed at the level of the anterior aspect of the soft palate together with the distal part of the muscle of the uvula, making a posterior mucous flap which, depending on the techniques, may have a rectangular or triangular shape.

This is in turn tipped forward and sutured to the edges of the incision. Depending on the techniques, more or less abundant resections of the uvula or incisions of the soft palate can also be performed. Then the two palatine pillars are sutured together if tonsillectomy was performed. This flap must have an adequate thickness in so as to avoid that the new palate is excessively thick. A possible dehiscence of the sutures creates functional and subjective difficulties. The duplication of the flap on a palate is often not without functional and subjective problems.

There are few data in the literature regarding the treatment of snoring, while there is some study about the treatment of OSAS, but from the limited data available and the extreme similarity of the technique to the more conservative UPPP is possible to assume that they have comparable results.

Laser Uvulopalatoplasty (LUPP) and Laser Assisted Uvulopalatoplasty (LAUP)

The LUPP introduced by Carenfelt [44] in the late 1980s was similar to classical UPPP under general anesthesia, but used the CO₂ laser for incisions. In 1990 Kamami [45] completely modified the technique, developing a procedure under local anesthesia in several sessions called LAUP. This technique in the 90s due to its simplicity of application has quickly taken off in Europe and the USA, with the appearance of innumerable variants. In general, the technique involves two paramedian incisions of the palate, at full thickness, from both sides of the uvula with a height of 1-2 cm. And a total or partial uvulectomy. The technical variants include variants in which the intervention was performed in a single step and variants performed in different sessions. Subsequently some authors, given the scarce results obtained and the frequent complications, started to develop more conservative techniques on the palatal musculature, removing only the mucosa at the palatoglossus muscle

level, while the uvula and the posterior pillar were treated as in the LUPP or LAUP [46]. From the results obtained, the LAUP was less effective than UPPP in the reduction of snoring, nocturnal awakenings, daytime sleepiness and apneas. It is also a very painful technique and in multi-step procedures about 20% of patients refused to undergo another session because of pain [22]. Furthermore the complications were very frequent.

Therefore, due to poor results and frequent side effects from the early 2000s, LUPP and LAUP are not recommended as surgical procedures. In 2001, the Standards of Practice Committee of the American Academy of Sleep Medicine issued some guidelines regarding the LAUP advising against its use [23].

Lateral Pharyngoplasty (LP)

It is the first technique to pay significant attention to the role of the lateral wall of the pharynx in the determinism of the OSAS. Developed by Cahali [32] in 2003 it has as a fundamental premise the stiffening of the lateral wall of the pharynx. In fact the obstruction linked to the lateral walls of the pharynx is the only risk factor, besides BMI and neck circumference, which acts independently in the determinism of the OSAS in man [48].

Cahali in the indications inserted the presence of at least two of the following characteristics:

- Lateral peritonsillar narrowing (defined as the size of peritonsillar tissues greater than 25% of the pharyngeal space, calculated as the internal distance of the mandible measured in the middle of the tonsillar fossa);
- tonsillar hypertrophy (defined as lateral bulkiness of the tonsils greater than 50% of the distance between the posterior tonsillar pillars);
- ptotic soft palate (which does not allow visualization of the posterior pharyngeal wall).

In addition to these assumptions, the subjects had to present to the fiber optic pharyngoscopy a narrowing or collapse in the retropalatal region without narrowing in the hypopharynx, both at rest and during the Müller maneuver.

The first step of the surgical procedure is tonsillectomy with identification of the palatoglossus and palatofaryngeal muscle. Then they identify and raise the fibers of the upper constrictor muscle of the pharynx at the level of the tonsillar fossa, as far as possible from the glossopharyngeal. Once detached from the lateropharyngeal space, the upper pharynx constrictor is sectioned in a cranio-caudal direction obtaining two muscular flaps. The medial flap is left in situ, while the lateral flap is sutured anterior to the palatoglossus muscle. Then a Z-plastic is made between the mucosa of the anterior aspect of the soft palate and the upper portion of the palate-pharyngeal muscle, covering the upper part of the tonsillar fossa, while the lower part of the loggia is closed by suturing the remaining part of the pharyngeal palate muscle to the anterior pillar.

With the suspension to the palatoglossus muscle Cahali tries to give support to the oropharynx and the tongue. While with the Z plastic, he tries to orient the scar retraction laterally.

The technique has several side effects such as persistent pain, reflux of fluids from the nose. But the main complication due to the section of the upper pharyngeal constrictor is lasting dysphagia especially for solids.

In a subsequent article Cahali [48] reports the improvement of post-operative swallowing recovery with the preservation of the stylopharyngeal muscle that was frequently sacrificed. But the main risk is related to the section of the upper pharynx constrictor is the exposure of the parapharyngeal space with its important neuro-vascular structures.

Expansion Sphincter Pharyngoplasty (ESP)

Even ESP is based on the fundamental concept that at pharyngeal level the obstruction linked to the collapse of the lateral walls of the pharynx plays a fundamental role. This technique was developed by Pang and Woodson in 2007 [49], and is currently one of the most applied pharyngoplasty, even by our group [50], since it is effective and less invasive than lateral pharyngoplasty.

The main indications are:

- Predominantly lateral pharyngeal collapse
- Wide and thick posterior pillars
- Thick soft palate

It has specific contraindications, in addition to the general ones for palatal surgery, in the event of:

- Absence of lateral pharyngeal collapse
- Tonsillary pillars fused together
- Very thin soft palate
- Scar palate

The first step of the surgery consists in bilateral tonsillectomy with identification of the palato-glosso and palato-pharyngeal muscle and preservation of the covering mucosa. The palato-pharyngeal muscle is then isolated from the surrounding tissues, preserving the fibers of the upper pharyngeal constrictor. At this point, two ligatures are placed at the level of the distal margin of the muscle, to keep the muscle fibers together and to ensure better hemostasis, since the muscle is sectioned downwards creating a superior hinged muscle flap, in part connected to the upper constrictor of the pharynx.

At this point, the original technique involves an incision of the palato-glossus muscle fibers at the palatine arch plane and the suture of the distal portion of the flap at this level, and the subsequent suturing of the superficial mucous planes. In our experience this passage was modified by creating a tunnel with a klemmer forceps in the context of the soft palate with a 45° angle in the direction of the pterigoid hamulus, tipping the muscular flap inside the tunnel and fixing it with two resorbable stitches in position, obtaining an antero-lateral palate stretching [50]. At this point the palatine pillars are joined with a resorbable suture. A partial uvulectomy is performed depending on the laxity of the uvular mucosa.

Patients are monitored post-operatively for a few hours with pulso-oximetry and an adequate pain therapy is administered, since for the first post-operative week there is pain on swallowing.

Pang et al. do not report complications such as reflux of fluids from the nose or palatal insufficiency, palatal fistulas or oral infections. Which did not even occur in our experience. But unlike the author we reported 2 cases of post-operative haemorrhage, occurring in the first operations, probably linked to the inevitable learning curve.

The key points of the surgery are:

- The increased space at the transverse level at the level of the pharynx both for the removal of the tonsils and for the dislocation of the palato-pharyngeal muscle
- The incomplete isolation of the palato-pharyngeal muscle from the upper pharyngeal constrictor thanks to which it creates sufficient tension on the side walls
- ESP also tends to widen further, in the anterolateral sense, the space at the level of the oropharyngeal vestibule during the healing phases, since the cicatricial retraction of the palate-pharyngeal muscle flap stretches the palate and the lateral walls of the pharynx even more in this sense by creating centrifugal healing vectors. Contrary to UPPP where the healing vectors were centripetal with a progressive worsening of the results obtained.

Pang et al. [49] showed a significant improvement in AHI compared to UPPP, with a percentage of surgical success according to the Sher criteria of 82.6% for ESP against 68.1% for UPPP, with a significant difference in oropharyngeal transverse diameters post-operative where after ESP the residual transverse collapse with Muller maneuver was modest, while after UPPP it was still very evident.

In our experience ESP has proved to be an effective weapon in the management of palatal obstruction. In fact in patients subjected exclusively to ESP due to the presence of a predominantly palatal obstructive site, an improvement in AHI was obtained, which on average was reduced by 63.4% with a success rate according to the Sher criteria of 65% [50]. We have also shown in all patients subjected to ESP a notable improvement as regards the anatomical parameters at the oropharyngeal level. In fact, a notable dilatation of the transverse diameters and a progression of the palate considerably higher than the UPPP, with a reduction of the oropharyngeal collapse to the Müller maneuver equal to 64.7%.

Relocation Pharyngoplasty

This technique introduced in 2009 by Li and coll. [51], based on the increase in the volume of the pharyngeal vestibule acting on the lateral walls of the pharynx, with a technique similar to that of Cahali [32]. After tonsillectomy with careful conservation of the mucosa of the palatine pillars. The pharyngeal palate muscle is taken near the uvula and rotated upwards and sideways making it approach the remaining part of the soft palate.

The full-thickness tissue of two elliptical zones at the level of the soft palate is removed, including mucosa, submucosa, adipose tissue and muscle. The upper pharyngeal constrictor is sutured to the homolateral palatoglossus muscle with a cranio-caudal direction. The palatal-pharyngeal muscle is separated from the upper constrictor of the pharynx to facilitate tension-

free approximation. The pharyngeal palate muscle with its mucous flap is then anteriorized and also sutured on the palatoglossus muscle. Finally, a partial uvulectomy is planned.

With this technique a single, rigid and anterior newly formed palatine is created, which puts the lateral walls of the pharynx in tension and increases the posterior space because the advancement of the posterior pillar also brings with it the dorsal portion of the palate.

The results show a significant reduction in snoring of daytime sleepiness and AHI. No post-operative bleeding, reflux of liquids from the nose or alterations of the voice were found.

This technique, unlike that of Cahali, does not involve a dissection of the upper pharyngeal constrictor with consequent opening of the lateropharyngeal space and the risk of damaging the important neuro-vascular structures contained in it.

Anterior Pharyngoplasty

It consists of a technique of palatal tightening introduced for the first time by Pang in 2008 [52], indicated in the treatment of snoring and mild-moderate OSAS associated with tonsillectomy. Pang performed the procedure under local anesthesia if it was not associated with tonsillectomy in the case of absent or small tonsils (grade 0-2) or in general anesthesia when associated with tonsillectomy (grade 3-4 tonsils). In our experience we have always preferred to carry out surgery under general anesthesia.

The technique consists in practicing a partial uvulectomy, removing only the mucosa. Followed by the removal of a rectangle of anterior mucosa of the palate about 40-50 mm long and 7-10 mm high, until the underlying musculature is uncovered. And then after haemostasis, the two upper and lower flaps are gathered together with absorbable sutures anchored at full thickness in the musculature of the palate, creating an elevation and anteriorization of the palate. Pang reported no major complications and showed improvement in snoring and sleepiness in all patients, with an improvement in the IHI according to Sher's criteria of 71.8%. The only negative effect reported is a modest post-operative pain, greater in the case of tonsillectomy.

In 2014 Salamanca and coll. [53] proposed a modification of the technique, the Barbed anterior pharyngoplasty, introducing the use of self-locking "hooked" wires (QUill® knotless tissue closure device, angiotech Pharmaceutical inc., Vancouver, Canada). The technique involves a rectangular incision like that made by Pang, the closest possible to the pterygoid hamulus where the muscle suture is anchored to be fixed to bone structures. Then with a continuous suture the muscular part of the palate is sutured. And then the same procedure is repeated on a submucosal level.

At this point, to further stabilize the palate, a suture is made by anchoring the palate to the posterior nasal spine and bilaterally to the pterygoid hamulus and to the mandibular raphe creating a suspension of the edge of the soft palate and the posterior palatine pillars.

Obtaining at the end of the procedure a palate shortened and projected forward. The only reported side effect was a modest uvular edema and moderate pain for about ten days. Within 4-6 weeks the final fibrosis and consequent stiffening of the palate was obtained.

Barbed Reposition Pharyngoplasty (BRP)

This new technique developed by Vicini et al. [54], arises from the idea of using self-locking wires applied to a technique similar to relocation faringoplasty [51]. It is based on the principle that the palatine pillars and the palate are considered as a tripod and weakening the

posterior palatine pillar and moving it forward tends to unbalance the whole system forward increasing the mesopharynx space. The first step consists in tonsillectomy with careful preservation of the mucosa of the anterior and posterior pillars, therefore the lower portion of the palate-pharyngeal muscle is partially incised weakening it. Then a full-thickness mucosa and muscle triangle is removed at the upper lateral edge of the tonsillar loggia to obtain a wider and more squared space at the level of the pharyngeal vestibule. The needle is then introduced at the level of the posterior palatal spine, made to pass completely through the palate in a lateral direction, then around the pterigo-mandibular raphe and is taken out of the bed of the tonsillectomy and then passed through the upper part of the palate muscle pharyngeal making it come out near the mucosa of the posterior pillar, but not crossing it. Then the needle is passed again through the palatopharyngeal muscle and through the raphe by suspending the posterior pillar. By allowing the posterior pillar to be positioned in a more lateral and anterior position, this passage is repeated several times up to the most distal part of the palate-pharyngeal muscle and therefore the thread is passed through the soft palate blocking it.

This technique is currently the most used in our group with excellent results both for snoring and apnea. The only side effect was the pain and the sense of foreign body, which is reduced within a couple of weeks.

Hypopharyngeal Surgery

Hypopharyngeal surgery is basically divided into hyoid surgery and tongue surgery.

Hyoid Surgery

The hyoid surgery consists mainly of the thyro-thyroid disease or suspension of the hyoid. Represents the most reviewed and most documented mode of management of hypopharyngeal collapse, especially on the side walls. The modern surgical procedure, according to Ryley [55] is not very complex, rapid and relatively effective, especially in the range of moderate OSAS even if it is undergoing a progressive decline in recent years as it is considered no longer valid in the management of hypopharyngeal collapses and therefore used only in some selected cases in association with the plastic of the palate.

The indications are:

- Moderate OSAS
- Presence of obstruction at the retrolingual level

A horizontal skin incision of about 3-4 cm is made at an intermediate distance between the inferior edge of the hyoid and upper edge of the thyroid cartilage, possibly at the level of a skin fold. Once the hyoid is identified, a myotomy of the muscles inserted on it is performed, this varies according to the authors. According to the original technique the infrahyoid muscles are completely detached and the hyoid ligaments are dissected from the lesser cornu, while the suprahyoid musculature is left intact.

In our experience we prefer to dissect both the suprahyoid and subhyoid muscles, up to the level of the lesser cornu, leaving the stylohyoid ligament intact. In this way we obtain a better

mobilization of the hyoid that allows us to overtake the anterior margin of the thyroid cartilage in pexia, but still maintains a good traction on the musculature of the lateral walls of the pharynx which is largely adherent to the great cornu of the Hyoid. This allows the side walls of the pharynx to be in tension and the base of the tongue to advance. At this point the pre-thyroid muscles are separated medially, to allow the identification of the thyroid notch, and the thyroid pexia is performed by 2 points per side with Vicryl n° 1, while in the meantime trying to gently draw forward the iode in the attempt to make them overtake the upper edge of the thyroid cartilage. If the traction is excessive can happen that fractures the hyoid, in these cases it is sufficient to proceed with pexia correctly and usually has no influence on the outcome of the surgery. Normally a small drainage is placed, the muscles above and below the hyoid and all the subcutaneous planes are recovered and then the skin is closed with an intradermal suture.

The surgery does not present any particular post-operative pain, there may be a transient dysphagia which usually resolves in a few days [71]. Rarely, other post-operative complications may occur, such as the most frequent hematoma, seroma, scarring and transient joint distortion. Only Riley assessed the efficacy of the ioidea suspension as a single intervention in the treatment of OSAS, with a 53% success rate.

Tongue Surgery

The tongue surgery is a field that over the years has become increasingly wider, because it is adding numerous techniques ranging from minimally invasive radiofrequency surgery to partial glossectomies. The procedures can be roughly grouped into three categories: tongue reductions, glossopepy and glossectomies.

Tongue Reductions

Most authors perform this procedure by applying radiofrequencies, which represent the single least invasive procedure on hypopharyngeal obstruction and vibration.

The indications are represented by:

- Predominantly lymphatic lingual base hypertrophy
- Simple non-palatal snoring
- Mild to moderate OSAS with predominant retro-lingual obstructive component

It is the only hypopharyngeal procedure that can be performed under local and outpatient anesthesia. Depending on the device used, 8 to 16 applications are used, the application pattern is variable. The main precautions are to avoid repeating the inflexion in the same spot and to avoid an excessive duration of the application such as to cause thermal damage to the mucosal level, which creates an important pain and consequent dysphagia for a few days. It is however preferable to have one night of observation after the treatment.

The most severe complication, although not frequent, is the abscess of the base of the tongue [56]. The ulceration of the lingual base mucosa is much more frequent, usually due to too superficial or prolonged application of the electrode.

Glossopexy

The glossopexy are techniques based on the application of devices for containing and anchoring the base of the tongue, aimed at preventing its posterior collapse.

In fact various kits have been developed including the best known is the Repose system (Influ-ENT, USA). It consists of a non-resorbable suture that is passed with two loops around the base of the tongue and then fixed thanks to a screw at the inner edge of the chin [57].

The technique was almost completely abandoned due to the partial results, average success rate of 32.6%, comparable to the less invasive RF.

Another technique is the one developed by Woodson [58] with the ADVANCE system which consists in the surgical positioning of an anchorage system of the midline tissue of the posterior portion of the tongue connected to an anchorage at the level of the adjustable mandibular bone with a flexible tether. But the high failure rate from anchoring in the tissue of the device precluded its clinical use.

Glossectomy

A factor to be carefully evaluated in tongue base surgery is the rich vascular network provided by the lingual artery. According to Vicini et al. [59] the base of the tongue does not offer safe and reproducible landmarks, except for a rich arterial network that approaches the constantly present midline. And theoretically this can be used as an anatomical plane above which there are no large nerves or vessels.

Trans-cervical resection of the base of the tongue was developed in the 1990s by Chabolle et al. [60] when even minimally invasive volumetric reduction techniques were not available. For these reasons this technique has been totally abandoned.

Subsequently, several techniques of transverse oral lingual resection have been proposed.

Woodson and Fujita [61] recommend the excision of the front corner of the resection of a 3 cm side wedge in order to create a defect.

Because of their invasiveness and post-operative morbidity these techniques are considered reserved for patients with severe OSAS who are not compliant with nCPAP therapy. It can be considered an alternative therapeutic option in severe apnea in overweight subjects as an alternative to bimaxillary advancement.

Thanks to the emergence of new technologies, some authors have tried to overcome the highly invasive technique. The former were Maturo and Mair [62] using the plasma-mediated bipolar radiofrequency technology (coblator) and then Friedman et al. [63] who developed the submucosal minimally invasive lingual excision (SMILE). This technique involves the prior identification of the course of the lingual arteries with doppler. He then proceeds to a medial incision with a cold blade scalpel, then proceeds with tissue removal with coblator with movements from the top down, paying attention to stay within 1 cm from the median line and medial to the previously marked arteries.

The advent of trans oral robotic surgery (TORS) has allowed the emergence of a further alternative in the management of the lingual base, similar to what happens with oncological surgery.

Lee et al. [64] achieved a 45% success rate in the treatment of severe OSAS with lingual tonsillectomy with TORS and UPPP, with an average AHI reduction from 55.6 to 24.1.

Friedman et al. [65] compared the efficacy of TORS in the management of obstruction of the base of the tongue with that of the coblator and the RF. In none of the 3 groups were major bleeding reported, with similar post-operative pain. The average AHI reductions were

60.5% $\pm$ 24.9% for TORS, 37.0% $\pm$ 51.6% for the Coblator and 32.0% $\pm$ 43.3% for radiofrequency, respectively. Furthermore the authors affirmed the possibility and safety of performing the TORS for the lingual base without the need for tracheotomy.

Vicini et al. [66] with lingual tonsillectomy with TORS obtained a reduction of AHI from 38.3 $\pm$ 23.5 to 20.6 $\pm$ 17.3 with no particular pain-related disorders, difficulty swallowing and no particular complications. Therefore he claims that in case of important hypertrophy of the base of the tongue, minimally invasive techniques are absolutely insufficient and only an adequate removal of tissue can effectively increase the space. Therefore the TORS can be considered in some cases a valid alternative also to the bimasillary advancement in the management of obstructions at the base of the tongue, with a more easily acceptable post-operative course.

HYPOGLOSSAL NERVE STIMULATION

In recent years, thanks to technological progress, the neurostimulation of the lingual musculature during the night is being re-evaluated. In the past the major limitation of these stimulation techniques was the continuous induction of arousals that equally compromised the architecture of sleep [67, 68]. The solution to this problem has been found through selective stimulation of the hypoglossal nerve, which mainly contains efferent motor fibers that give a minimum sensitive afferent feedback.

The musculature of the tongue consists of extrinsic muscles and intrinsic muscles, both groups innervated by the hypoglossal nerve, except the palatoglossus which is innervated by the pharyngeal plexus.

It is above all the stimulation of the genioglossus that has the greatest role, as it represents the major dilator of the VAS, allows the protrusion of the tongue and the tension of the anterior pillars.

The neurostimulator is implanted under general anesthesia, through a small submandibular incision. Then the hypoglossus is exposed inferiorly to the submandibular and above the tendon of the digastric. Once the nerve is isolated, the cuff with the electrodes is placed on the main nerve trunk distal to the branch that innervates the retrusor muscles. This is done thanks to the intraoperative nerve stimulation which allows to identify the correct level to which the neuro-stimulator can be applied based on the muscular response obtained. In the case of neuro stimulators with thoracic sensor, the sensor is tunneled subcutaneously in the ipsilateral infraclavicular space. After 30 days the device is activated and the patient is subjected to a night polysomnography for titration, in order to find the difficult balance between stimulation and tolerance without arousals.

Certal and coll. [69] in a recent review they compared the effectiveness of existing systems, highlighting an improvement in the AHI, the overall reduction in the AHI was 54% at 3 months, 57% at 6 months, and 50% at 12 months.

None of the analyzed studies reported serious side effects, but in 4.5% of patients it was necessary to resort to explanting the device. The defined indications were BMI $\leq$ 32 kg/m², AHI between 20 and 50 without complete concentric collapse at the level of the soft palate, patients with bulky tongues reported better results. They noted some technical differences in particular with regard to the multi-electrode system that only targets the desired parts of the

hypoglossal nerve, allowing a high degree of specificity. The targeted activation of the genioglossus muscle avoids the need to synchronize stimulation with the respiratory cycle and can reduce some of the costs related to surgical time.

Laryngeal Surgery

Although the most frequent obstruction sites are those in the retropalatal and retrolingual level, the larynx can also contribute to the genesis of OSAS. It is essential to distinguish pediatric forms from those of adults, as in the former the main causes of obstruction are laryngomalacia, malformations and only rarely from neoformations, neoplasms or laryngeal paralysis. While in the adult the causes are specularly opposite.

Laryngeal obstruction plays a minor role in the adult compared to the child in the determinism of the OSAS.

Possible anatomico-functional conditions to be treated:

1. laryngeal diplegia;
2. laryngeal monoplegia;
3. floppy epiglottis;
4. tumors;
5. post radiotherapy larynx;
6. post-reconstructive neolarynx;
7. acquired laryngomalacia (laryngeal trauma, sarcoidosis, acromegaly, etc.);
8. stridor from MSA;

In the case of floppy epiglottis, a partial resection is indicated, usually V or horizontal in the free part associated with a shortening of the glosso-epiglottic ligament [70].

It is essential to use sleep-endoscopy in cases with suspected laryngeal obstruction, since CPAP therapy is not possible in the case of floppy epiglottis because positive pressure air presses the epiglottis against the laryngeal vestibule as if it were a lid, worsening the situation [72]. In these cases, there is no alternative to surgery. The decisive criterion is not the size of the epiglottis but its rigidity. In the case of very flaccid epiglottids, a partial resection should be considered, but if the cause of the prolapse is related to the posterior thrust operated by the base of the tongue, it is on this that one must act with a volumetric reduction or with hyoid advancement.

FACIAL SKELETON SURGERY

Unlike the interventions described above, it acts on the container and not on the content, allowing an extension of the UA. It is very effective being comparable to CPAP but it is also very invasive and has relevant anatomical and aesthetic modifications.

There are numerous groups of different procedures reviewed on the facial skeleton:

1. Advancement of the isolated genioglossus muscle or integrated with other procedures: This procedure is practiced entirely orally through an incision on the gingival mucosa, creating an advancement of the base of the tongue.
It represents an invasive technique, with a high risk of complications, it has been replaced by most groups by less invasive techniques such as RF of the base of the tongue.
2. Isolated mandibular advancements.
3. Maxillo-mandibular advancements: Designed by Kuo et al. [73], today it is surgery with the greatest success rate after tracheotomy. But it is a complex and invasive intervention with high morbidity and complications, and considerable aesthetic consequences. It allows the simultaneous dilation of all the rhino-hypo-pharyngeal structures thanks to the increase of the volumes of the UA with tensioning of the lateral walls of the pharynx and advancement of the soft palate and the base of the tongue. It is one of the few surgical procedures that does not require an oropharyngeal time on the palate. Many studies have shown the effectiveness of maxillo-mandibular progress compared with CPAP. In a meta-analysis and systematic review of the literature Holty et al. [74] showed an average reduction in the AHI from 63.9/h to 9.5/h.
4. Rapid expansions of the upper jaw.
5. Anterior and transverse maxillary osteodistraction procedures: It is used when the advance must be greater than 10 mm or in children, as progressive progression reduces the risk of alveolar nerve injury. The procedure involves osteotomies similar to AMM, but these are mobilized only progressively (usually 1 mm per day) after a few days under the guidance of distractors. Thus non-mineralized tissue fills the osteotomy gap which is slowly lengthening and after the end of distraction it will turn into bone during the consolidation period. Since there are multidirectional distractors, it is possible to correct the distraction vector during treatment.

TRACHEAL SURGERY

Tracheotomy was the first effective treatment on OSAS and still remains the last but most certain resource [75].

It is indicated in some cases

1. In urgency: in case of newborns with severe respiratory distress, also due to VAS malformations, following surgical complications.
2. Pending: in the presence of laryngomalacia with severe OSAS, or in children with facial cranial anomalies awaiting surgery
3. Alternatively; to CPAP or other types of surgery especially in the case of patients with morbid obesity.
4. In recovery of techniques, however indicated in the most serious cases (advancement of bilaxel or Chabolle) did not go well.

The success rate is close to 100%, but in patients with cardiopulmonary decompensation the tracheostomy reduces drastically but does not eliminate the OSAS problem probably due to the persistence of central events, and in some cases due to the occlusion of the ostomy by the tissue exuberant fat.

In adult patients in the rare cases in which the tracheotomy is a procedure of choice in our experience, it is preferable to perform a so-called “skin lined” technique [76] in which the edges of the tracheostoma are covered laterally and upper-inferiorly by two flaps of tracheal mucosa. This technique allows to obtain a more stable tracheostoma, which does not undergo the formation of granulation tissue and allows the eventual daily occlusion.

BARIATRIC SURGERY

Bariatric surgery is indicated for significant weight loss in patients with BMI > 40 kg/m² or in those with BMI ≥ 35 kg/m² but with important comorbidities and where dietary recommendations were not successful. This therapy should be implemented in conjunction with ventilatory therapy, and the severity of the OSAS should be re-evaluated following weight loss. A reduction in OSAS has been reported, following weight loss after two years of bariatric surgery of 40% [77].

Chapter 103

LAPAROSCOPIC SURGERY IN SITUS INVERSUS

Pankaj Kumar*, Tushar S. Mishra and Siddhant Sarthak

Department of General Surgery, AIIMS Bhubaneswar, Odisha, India

ABSTRACT

Laparoscopic surgery have certain undisputed advantages over open surgeries. Less pain, early recovery, better cosmesis, early return to work and increasing expertise have prompted surgeons to offer the minimal access surgery for wider spectrum of indications.

Situs inversus is a condition where the anatomy is sagittally reversed like a mirror image. With better understanding of the anatomy, ergonomics and availability of robotic surgery, numerous minimally invasive surgical procedures has been reported in patients with situs inversus. This chapter will provide insight about laparoscopic surgeries done for various indications in patients with situs inversus along with the various difficulties and methods to address them.

Keywords: situs inversus, laparoscopy

INTRODUCTION

The first laparoscopic cholecystectomy in a patient with situs inversus was attempted by Camos and Sipes, in 1991 [1]. Since then various surgical procedures like splenectomy, gastrectomy, hepatectomy, esophagectomy, colonic resection and others have been successfully performed laparoscopically. The major challenge faced by most surgeons is adapting to the mirror image anatomy. Diagnosis of situs inversus preoperatively and adapting to the changed anatomy for better ergonomics is the key to safe and successful completion of surgery. Most surgeon still prefer open procedures in patients with situs inversus, because of technical difficulties like position of monitor, site of port placement, difficult dissection and long operative time. Reports of successful surgical procedures in many parts of the world have helped in better understanding of laparoscopic anatomy and

* Corresponding Author's Email: drpkushwaha@gmail.com.

technical difficulties encountered. But a comprehensive review of these challenges and various modifications is lacking. This chapter will discuss the ergonomics and challenges of laparoscopic surgeries in patients with situs inversus.

LAPAROSCOPIC CHOLECYSTECTOMY

Nearly seventy cases have been reported by now ever since it was first described in 1991. Most of the surgeons have used mirror image of conventional four ports of laparoscopic cholecystectomy. With experience and expertise single incision multiport cholecystectomy has also been performed recently[2].

The identification and orientation to the mirror image position of the biliary tree is the first step for successful completion of the surgery. The left-handed surgeons may actually benefit in a scenario of laparoscopic cholecystectomy in situs inversus. The right-handed surgeons however are more likely to face difficulty in dissection and delineation of Calot's triangle. Proper preoperative planning to adapt to the changed anatomy, including the port placement, position of the surgeon, assistant and the monitor would help in performing a safe cholecystectomy laparoscopically.

A mirror image strategy of the OR set up is recommended. The operating surgeon and camera assistant will benefit standing on the right side and the monitor to be above the patients left shoulder. Two 10 mm ports should be placed, one in the sub umbilical and the other epigastric, and two 5mm ports in the left midclavicular and in the left anterior axillary line. The suggested position of port, monitor and surgeon is shown in Figure 1. A 30-degree scope is recommended for the procedure. Although dissection of the Calot's triangle can be done by a right handed surgeon using epigastric port and left midclavicular port, the dissection is usually difficult, due to use of less used left hand. Hence the movements should be smooth and adequate time must be spent while performing the Calot's dissection. Most of the surgeons have reported major difficulty clip application, which requires both precision and power[3]. Surgeon may stand between the legs during dissection for better ergonomics. The assistant should hold the Hartmann's pouch, rather than fundus to prevent crossing of hands while retracting. The dissection should be carried out from lateral side of Hartmann's pouch remaining close to the gallbladder. The possibility of associated biliary tract and vascular anomalies is higher in patients with situs inversus partialis and they may require intraoperative cholangiography and conversion to open cholecystectomy[4]. Successful laparoscopic exploration of common bile duct for choledocholithiasis in a patient with situs inversus has also been reported[5].

Laparoscopic Gastrectomy

Laparoscopic radical gastrectomy is increasingly being performed these days with the standardization of the surgical technique, improved instrumentation, high definition imaging systems and advanced energy sources. Alteration of the anatomy makes laparoscopic gastrectomy in presence of situs inversus more difficult.

Figure 1. Suggested port placement for laparoscopic cholecystectomy.

Figure 2. Suggested port placement for laparoscopic gastrectomy.

The first case of laparoscopic distal gastrectomies (LADG)+ in situs inversus was performed in Japan, in 2003[6]. Since then more than thirty cases of laparoscopic gastrectomies have been performed for gastric carcinoma in patients with situs inversus. Most of these cases done are laparoscopic distal gastrectomies. The esophagojejunal anastomosis and the lymphadenectomy make laparoscopic total gastrectomy (LATG) technically more demanding and hence less frequently attempted. The first case of LATG with extended (D1+) lymphadenectomy was done by Morimoto et al. [7]. They took 359 minutes as against the average time of 267 minutes for LADG in the other reported cases.

Laparoscopic radical gastrectomy requires frequent change of position of the operating surgeon. The port positions also need to be altered for better ergonomics for doing this

procedure in patients of situs inversus. However there have been four cases where successful completion of the procedure has been reported without the surgeon changing the sides.

The mirroring of the images in situs inversus may confuse the surgeon during the surgery, which can potentially be hazardous. Hence only surgeons reasonably experienced with laparoscopic gastrectomy should attempt doing it. However, robot-assisted distal gastrectomy (RADG) is an exception to this, as the surgeon does not need to change his position during surgery because of the centered robotic view of the field with easy changing of the instruments between hands.

After creation of pneumoperitoneum, a 12 mm optical trocar should be placed at the umbilicus for the telescope. The working ports are placed in the left and right subcostal positions with additional 5 mm trocars laterally (Figure 2). The lymph nodal stations 5, 6, 7, 8a, and 9 are usually dissected with the surgeon standing on the right side of the patient and those in the stations 1, 2, 3, 4sa, 4sb, 4d, and 11p from the left side.

Laparoscopic Colon Resection

Laparoscopic colectomy has been reported only in 16 patients with SIT. It is a common belief that laparoscopic colonic surgeries with situs inversus are the same operations as without situs inversus, except for the mirror images. But the cases reported in literature have highlighted the difficulties related to the use of non-dominant hand during some critical steps. Various modifications have been suggested to improve the ergonomics during colonic surgery, to improve the outcome.

Right Hemicolectomy

The first laparoscopic right hemicolectomy was reported by Fuziwara Y et al. in 2007[8]. Since then three more cases have been done. Right hemicolectomy in SIT is relatively easier than the other colonic surgery. The major emphasis is to understand the mirror image anatomy by proper radiological investigation. The most important step in preoperative workup is identification of superior mesenteric artery on the left side. Under general anesthesia, the patient should be placed in the low lithotomy position with leg separated, head end and right side down to displace the small bowel away from the operating field. The operating surgeon and camera assistant are suggested to stand on the right side of the patient while the first assistant on the left. The suggested port position is similar to the sigmoidectomy in normal patient, i.e., 12 mm camera port either umbilical or 1 cm cranial and right to the umbilicus, working 12 mm port in right iliac fossa, another 5 mm working port in right flank, two 5 mm ports for the assistant on left flank and left iliac fossa (Figure 3). Mirror image anatomy must be visualized after creating the pneumoperitoneum. Medial to lateral dissection is preferred. The mesentery should be opened just caudal to the ileocolic vessel. Dissection should be continued cranially till anterior surface of duodenum is seen. The ileocolic vessels should be secured and divided near its insertion in superior mesenteric vein. Caecum and ascending colon is mobilized next with precaution to safe guard the ureter from injury. Division of colon and further anastomosis is similar to that of orthotopic hemicolectomy.

Figure 3. Suggested port placement for laparoscopic right hemicolectomy.

Sigmoidectomy

The laparoscopic sigmoidectomy has been attempted for diverticulitis and malignancy. In SIT, sigmoid colon is positioned on the right side instead of left. Laparoscopic sigmoidectomy in SIT should be operated in low lithotomy with leg separated or the position, according to the surgeon's comfort. The position of operating surgeon, camera assistant and first assistant should be mirror image of orthotopic patient. Hence operating surgeon and camera assistant should stand on the left side, while first assistant will stand on the right. The patient should be placed in the Trendelenburg position at 30 degree and right side up to displace the small bowel. Trocar positions used by various surgeons differ. The trocar placement used by Yaegashi et al. was similar to the standard laparoscopic colon resection with one additional 5-mm trocar in left lower quadrant[9]. While, Davies et al., Kobus et al and Karabay et al. changed the position of right iliac fossa 12 mm port to the left iliac fossa for insertion of stapler and camera[10]–[12].

We suggest 12-mm supra-umbilical trocar for the camera; 12-mm trocars in the left and right iliac fossae as working ports and for the introduction of the laparoscopic stapler, which can be used interchangeably; a 5-mm trocar in the right flank for traction and a 5-mm trocar in the left flank (Figure 4). After creating the pneumoperitoneum the anatomy must be revisited. Sigmoid colon will be seen on right side, liver on left and spleen on right. The next step would be the mobilization of sigmoid and descending colon using energy devices. The dissection should begin at the sacral promontory. Putting the traction on sigmoid colon by the first assistant using the right flank port will help in identification of inferior mesenteric artery. The right ureter must be identified during medial mobilization. The inferior mesenteric artery should be ligated distal to the origin of left colic artery. The inferior mesenteric vein should be dissected till its insertion, secured and divided. Since the position of rectum remain same in both the normal and situs inversus patients, we suggest to change the position of the team as in normal laparoscopic sigmoid colon resection i.e., surgeon and camera assistant on right

and assistant on the left side for the rectosigmoid division. The rectosigmoid junction can be divided using an articulating endoscopic linear stapler. Further surgery can be continued as in patients with normal anatomy.

Figure 4. Suggested port placement for laparoscopic sigmoidectomy, anterior resection and abdominoperineal resection.

Anterior Resection and Abdominoperineal Resection

The first laparoscopic total mesorectal excision and abdominoperineal resection (APR) in a patient with situs inversus was reported by Huh et al, in 2010 and Choi et al. in 2011 respectively [13], [14]. Cui et al. have recently reported a robotic anterior resection with natural orifice specimen retrieval in SIT patient [15]. Most part of the surgery including the patient and port positions is similar to the sigmoidectomy as discussed earlier. A five-port method is preferred. The surgeon and camera assistant should stay on the left during initial part of surgery. The procedure starts with incising the peritoneum at the root of inferior mesenteric artery. The inferior mesenteric vessels should be defined, clipped, and divided. The peritoneum of the sigmoid mesentery is next incised over the sacral promontory. An avascular plane between the mesentery and the retroperitoneum is developed. Descending colon and splenic flexure which would be present on right side of the patient should be mobilized in the same position. After the complete mobilization of colon, mesorectal excision is performed with surgeons and camera assistant changing the side on the right side of the patient. The further procedure is same as in the standard laparoscopic anterior resection or APR.

Laparoscopic Splenectomy

There is only one report of laparoscopic splenectomy in a patient with situs inversus [16]. It was successfully performed in 185 minutes with just 35 ml blood loss. The mirror image

anatomy made the procedure difficult for the right-handed surgeon, so they used the anterior approach through the subxiphoid area. Patient was kept in the left semilateral position, with the operating surgeon on the left side, camera assistant between the leg and the assistant on the right. Three 12 mm ports were inserted in supraumbilical area, subxiphoid region, and in the right axillary line and one 5mm port in the right subcoastal region. The dissection in this case was started with mobilisation of the lower pole by dividing the splenocolic ligament. Ultrasonic dissector was used to take down the adhesion and expose the anterior aspect of the hilum. It was followed with division of short gastric vessels using harmonic scalpel. The upper pole division of gastrosplenic and splenophrenic attachments was next done. The spleen was then lifted and an endoscopic stapling device was inserted from the subxiphoid port to divide the splenic vessels at the hilum. Finally, the last attachments to the retroperitoneum were divided to complete the procedure. We suggest proper preoperative planning and involvement of an experienced surgeon to perform splenectomy in these patients.

Laparoscopic Bariatric Surgery

Laparoscopic bariatric surgery has become the standard of care for patients with morbid obesity. Situs inversus in a patient undergoing laparoscopic Roux-en-Y gastric bypass (LRYGB) was first performed by Wittgrove, in 1998[17]. Since then 27 laparoscopic bariatric surgery have been reported in patients of situs inversus, in whom the entire range of bariatric series including Laparoscopic Roux-en-Y gastric bypass (LRYGB), banded Roux-en-Y gastric bypass (LBRYGB), laparoscopic adjustable gastric banding (LAGB), Laparoscopic sleeve gastrectomy (LSG), modified duodenal switch, Omega loop gastric bypass or mini gastric bypass, laparoscopic bilopancreatic diversion and Robotic assisted RYGB (RRYGB) have been performed.

A higher complication rate and a longer operating time has been reported in laparoscopic bariatric surgery in patients of Situs inversus, which could be due the unfamiliar anatomy caused by the visceral transposition of organs in the sagittal plane. The technical difficulty of this procedure multiplies as does the complication rates, especially when the diagnosis of Situs inversus is missed preoperatively.

Several technical challenges and ways to overcome have been reported. The mirror imaging technique, where the operating surgeon stands on the left side and alteration in the port positions are the only suggestion which has some consensus. Wittgrove described using the opposite hands and foot for handling instruments and operating the foot pedal respectively and needed double the usual time. Ahmed et al however could finish the entire procedure from the left side of the patient without the need for changing hands for the instruments unlike Whitgrove [18]. Wall et al described the first robot assisted RYGB in 2013[19]. The dexterity of the robotic arms obviated the need to change the position of the ports or of the surgeon during the surgery. Kassir et al. (2017), reported a mini gastric bypass with the patient in modified lithotomy and the surgeon standing in between the legs[20]. This position caused minimal confusion and the procedure was completed within the standard operating time. There was no need for any change in their port positions or in the position of the operating surgeon.

CONCLUSION

Laparoscopic surgeries can safely be performed in situs inversus patients with proper preoperative planning and with modifications in port placement and position of the surgeons and monitor and some amount of ambidexterity. Better understanding of ergonomics will definitely help in successful completion of laparoscopic surgeries in such patients. The experience in advanced laparoscopic surgery is an important factor to safely complete the procedure.

Chapter 104

MANAGEMENT OF SURGICAL WOUNDS INFECTIONS IN SPINE SURGERY

M. Dobran¹, D. Nasi¹, S. Veccia² and A. Giacometti²

¹Neurosurgery Clinic, Polytechnic University of Marche, Ancona, Italy

²Infectious Diseases Clinic, Polytechnic University of Marche, Ancona, Italy

ABSTRACT

Postoperative surgical wound infection (SWI) in the lumbar spine is unfortunately a common and potentially devastating complication. It is associated with increasing morbidity and the need for further surgery.

The rate of spinal wound infection in literature ranges from 0.7 to 11.9% . The type of surgery is perhaps the most significant variable affecting the rate of infection. When instrumentation is used for lumbar fusions, the infection rate increases and *Staphylococcus aureus* is the most common organism causing SWI. Other reported causative organisms include *Staphylococcus epidermidis*, *Enterococcus faecalis*, *Pseudomonas* spp., *Enterobacter cloacae* and *Proteus mirabilis*. Gram-negative bacteria are more common in trauma patients. White blood cell count is an unreliable indicator of infection. Erythrocyte sedimentation rate (ESR) may remain elevated for up to six weeks after surgery and C-reactive protein (CRP) levels normalize within two weeks. In regard to the potential role of Procalcitonine (PCT), recent trials demonstrated that PCT may be useful to diagnose neurosurgical patients with SWI.

Magnetic resonance imaging (MRI) is the most useful study to diagnose SWI. Gadolinium enhancement improves the diagnostic accuracy of MRI and it should be used whenever an infection is suspected. Rim enhancing fluid collections, ascending epidural collections, the evidence of bone destruction and progressive marrow signal changes are suggestive of infection. The nonoperative treatment of postoperative spinal wound infections is rarely indicated and it is generally limited to significantly immunocompromised patients.

Treatment of SWI is centered on the surgical debridement of all necrotic tissue and the obtainment of intra-operative cultures to guide antibiotic therapy. We recommend the involvement of an infectious disease specialist to adjust and monitor the efficacy of the antibiotic treatment. In most cases, SWI can be adequately treated while leaving spinal instrumentation in place. For severe SWI, repeat debridements, delayed closure and the

involvement of a plastic surgeon may be necessary. In some patients the use of the VAC therapy may be useful for the wound closure. Proven methods to prevent wound infection include prophylactic antibiotics, meticulous adherence to aseptic technique, frequent release of retractors to prevent myonecrosis and shorter operative time.

Keywords: surgical wound infections; spine surgery; antibiotic; surgical debridement

INTRODUCTION

Postoperative surgical wound infection (SWI) in the lumbar spine is unfortunately a common and potentially devastating complication [1]. It is associated with increased morbidity and the need for further surgery [2]. Additionally, the increasing prevalence of antibiotic-resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA) presents new challenges for both prevention and treatment of SWI, especially in patients with spinal instrumentation [3]. In this chapter, we review the epidemiology, the clinical presentation, the diagnosis and management of SWI.

EPIDEMIOLOGY

The rate of spinal wound infection in literature ranges from 0.7 to 11.9% [4]. The type of surgery is perhaps the most significant variable affecting the rate of infection. Simple lumbar discectomy carries a risk of infection of less than 1% thanks to shorter operative times, minor muscle trauma and generally healthier patients than those requiring more extensive spinal procedures [5]. When more extensive decompression is performed, with no fusion, the risk of infection increases from 1.5 to 2% [5]. With the addition of fusion to the procedure, operative time becomes longer, blood loss is greater and a separate operative site is usually required to harvest bone graft. The overall complication rate associated with a separate bone graft site is nearly 20%, some of them due to infection [6]. When instrumentation is used for lumbar fusions, the infection rate escalates from 2 to 6% [7].

Koutsoumbelis et al. [8] recently reviewed a consecutive series of 3,218 patients who underwent posterior lumbar instrumented arthrodesis. The surgery-related risk factors identified by their study included: (1) the presence of more than ten people in the operating room (OR), specifically cautioning against the presence of extraneous staff; (2) the long duration of surgery; (3) great intra-operative blood loss, the need for transfusion and (4) incidental durotomy.

Regarding patient-related risk factors for SWI, several studies reported the following factors: smoking, diabetes mellitus, alcohol abuse, obesity, malnutrition, advanced age, pre-operative hospitalization longer than one week and corticosteroid use. Smoking and diabetes have been shown to predispose patients to infection by inducing tissue ischemia and microvascular damage [9-11]. The thick layer of adipose tissue in obese patients provides a large potential space following surgical wound closure, which has poor vascular perfusion and may become necrotic.

Staphylococcus aureus is the most common organism causing SWI [12]. Recently, however, MRSA has become increasingly prevalent with 34% of SWIs according to the

positive cultures in the series by Koutsoumbelis et al [8]. Other reported causative organisms include *Staphylococcus epidermidis*, *Enterococcus faecalis*, *Pseudomonas* spp., *Enterobacter cloacae* and *Proteus mirabilis*. Gram-negative bacteria are more common in trauma patients.

PREVENTION

The meticulous adherence to aseptic technique is the single most important component of SWI prevention [13]. The use of prophylactic antibiotic therapy has significantly decreased the rate of SWI after spinal surgery. Finally, frequent release of retractors to prevent myonecrosis, debridement of any necrotic appearing muscle and irrigation at the end of the procedure are recommended [14].

CLINICAL PRESENTATION

The overall diagnosis of SWI must be made using clinical judgment and taking into account any available information. SWI can be defined according to his anatomic relationship to the fascia (superficial or deep). In the early postoperative period, the most common signs of infection are increasing pain at the surgical site, open wound, metal protruding through skin, prominent metal ware, abscess and fluctuant wound. Objective findings on examination include peri-incisional erythema, tenderness to palpation, induration and drainage. Constitutional symptoms such as fever or chills are especially concerning revealing clues.

DIAGNOSIS

White blood cell count is an unreliable indicator of infection. The acute phase reactants are more useful to diagnose infection, but they must be interpreted. Erythrocyte sedimentation rate (ESR) may remain elevated for up to six weeks after surgery. C-reactive protein (CRP) levels normalize within two weeks. Consequently, CRP has been shown to be a more sensitive indicator of the presence of SWI [15].

In regard to the potential role of Procalcitonine (PCT), recent trials demonstrated that PCT may be useful in the diagnosis of neurosurgical patients with post-operative fever. Nevertheless other authors showed that CRP is more sensitive compared to PCT in patients with SWI [16].

Plain radiographs of the spine are rarely useful for the diagnosis of early infection. In the setting of discitis, there may be evidence of disc height loss and end plate erosion. In latent infections, lucencies may be present around the hardware. Magnetic resonance imaging (MRI) is the most useful study to diagnose SSI. Gadolinium enhancement improves the diagnostic accuracy of MRI and it should be used whenever an infection is suspected. Rim enhancing fluid collections, ascending epidural collections, evidence of bony destruction and progressive marrow signal changes are all suggestive of infection.

MANAGEMENT

Today titanium instrumentation in spine surgery grants an advantage: titanium alloy is less prone to colonization than stainless steel. Titanium is handy and widely used in spinal stabilization in traumatic and degenerative pathologies of the column. In vitro studies suggest that the biofilm can block antibiotics, phagocytes and other humoral immune responders, making the infection relatively resistant to host defensive mechanisms and antibiotics. When a wound infection occurs in stabilized patients, the nonoperative treatment is rarely indicated and it is generally limited to significantly immunocompromised patients following an initial procedure involving irrigation and debridement to allow open-wound healing by means of secondary intention, dressing changes and wound packing.

Eradication of infection, however, nearly always requires careful debridement. Debate continues in literature about the need of serial debridements and their correct technique, if any, to close the skin and the fascial defect.

Debridement should consist of aggressive removal of all necrotic tissue and foreign materials such as sutures. Once the superficial layer has been debrided and irrigated copiously, the fascial layer must be inspected. This may be left unopened only if the surgeon is totally sure that the infection is only superficial. Once the deep layer is opened, debridement of necrotic muscle and significantly necrotic bone graft should be performed. In our experience and in literature, the leading philosophy is not to remove consolidating bone graft and instrumentation unless the infection is not healing in spite of debridements [1-5;16,17]. Instrumentation serves to stabilize the motion segment, theoretically decreasing inflammation and promoting bone healing. Some authors do not agree with leaving instrumentation in a contaminated wound. Non-essential spinal instrumentation such as loose pedicle screws should be removed. Anyway infection increases the risk of developing a pseudarthrosis and these patients must be closely monitored with serial imaging studies [18]. In cases of late infection with a solid fusion, instrumentation can be removed at the time of surgical debridement to facilitate the clearance of the infection.

Intra-operative tissue culture is essential to tailor antibiotic therapy before giving any. Close blood sugar control in diabetic patients and a nutrition consult in patients at risk for malnutrition are recommended [19-25].

It is a standard practice at our Institution to involve infectious disease specialists in the selection and serial monitoring of antibiotic therapy for SWI or other post-operative infections [26-28]. The antibiotic regimen is designed and monitored by an infectious disease specialist and based on the type of infectious organism and its drug sensitivity profile.

Intravenous antibiotic therapy is continued for at least six weeks postoperatively. In case of resistant organisms, such as MRSA, recent recommendations suggest extending intravenous antibiotic therapy for eight weeks [25]. At the end of the intravenous antibiotic therapy, we routinely maintain patients on oral suppressive antibiotics tailored to the infectious organism. The decision regarding the removal of the instrumentation versus lifetime oral antibiotic suppression is based on the causative pathogen, the patient's health status and the presence of a fusion mass. Recently, vacuum-assisted closure of postoperative spinal wounds after infection has gained in popularity, although only isolated reports have appeared in literature. This technique consists of an occlusive dressing over a suction drainage system. The vacuum effect draws the edges of the wound together removing any purulent tissue.

Success has been reported on a limited basis, but further trials need to be performed to determine any potential benefit compared with repeated debridement and tertiary closure or flap closures.

The necessary debridement of necrotic tissue following SWI may result in a significant soft tissue defect repaired with a muscle flap. This allows for high local antibiotic concentrations despite poor tissue vascularity. Multiple debridements are usually necessary and we recommend involvement of a plastic surgeon at early stage to grant an optimal wound management. Until today multiple techniques have been used for delayed wound closure. Negative pressure wound therapy (vacuum-assisted closure VAC) has been widely used for many years to treat complicated wounds and in case of failure of any surgical procedure. In many patients VAC therapy, also in presence of a wound infection, allowed the healing of the wound without removing the hardware. This is in line with the current trend to maintain the hardware in infected patients too.

In a recent study [28] we reviewed retrospectively 550 patients who underwent spinal fusion surgery from 2011 to 2015; 16 developed SSI after spinal instrumentation. The diagnosis of SWI was established according to positive wound swab or blood cultures and several clinical, laboratory and radiological findings. Additional pre-operative and intraoperative risk factors were analyzed. The incidence of SWI after spinal instrumentation surgery was 2.9%. Obesity was a statistically significant parameter ($p = 0,013$) that contributed to SWI along with alcoholism and/or drug abuse ($p = 0.034$).

The second study [27] on our patients documented that ESR and CRP values were statistically significant parameters to diagnose SWI after spinal implant. The leukocyte count, the number of lymphocytes and fever integrates the data of ESR and CRP with no statistical significance. MRI with contrast is the exam of choice, but FDG PET/CT may be useful in patients with a suspicion of SWI. Some pathogens have proved to be particularly hard to treat conservatively such as staphylococcus-MRSA. However some patients with SWI gain clinical healing with favorable outcome by means of target antibiotic therapy with no hardware removal.

In regard to the potential role of Procalcitonine (PCT), recent trials demonstrated that PCT may be useful to diagnose neurosurgical patients with post-operative fever. Nevertheless other authors showed that CRP is more sensitive than PCT in patients with SWI [15,16].

Plain radiographs of the spine are rarely useful to the diagnosis of early infection. In the setting of discitis there may be evidence of disc height loss and end plate erosion. In latent infections, lucencies may be present around the hardware. Magnetic resonance imaging (MRI) is the most useful study to diagnose SWI. Gadolinium enhancement improves the diagnostic accuracy of MRI and it should be used whenever an infection is suspected. Rim enhancing fluid collections, ascending epidural collections, the evidence of bony destruction and the progressive marrow signal changes are all suggestive of infection.

CONCLUSION

The treatment of SWI is centered on the surgical debridement of all necrotic tissue and the obtainment of intra-operative cultures to guide antibiotic therapy. We recommend the involvement of an infectious disease specialist to adjust and monitor the efficacy of antibiotic

treatment. In most cases, SWI can be adequately treated while leaving spinal instrumentation in place. For severe SWI, repeated debridements, delayed closure and the involvement of a plastic surgeon are necessary. Proven methods to prevent wound infection include prophylactic antibiotics, meticulous adherence to aseptic technique, frequent release of retractors to prevent myonecrosis and shorter operative time. To prevent myonecrosis, debridement of any necrotic appearing muscle and the irrigation at the end of the procedure are recommended [14].

ABSTRACT

In the 70s, B. Fisher described breast cancer as a systemic disease (biological determinism). This hypothesis suggested that results of the treatment of breast cancer depend exclusively on the extent of systemic dissemination produced before the disease was detected. This biological model determined a huge change in the treatment of breast cancer, considering that a less radical breast surgery could get a survival equivalent to that obtained with radical surgery but with less physical and psychological morbidity. Furthermore, administration of systemic therapy (chemotherapy and/or hormone therapy), whose action would be directed to the treatment of systemic disease at diagnosis, should improve survival and increase disease-free period.

Changes to less radical surgical techniques were progressive and began with conservative radical mastectomy (Patey-Dyson). No differences in survival and local recurrence among patients treated with conservative radical mastectomy and traditional mastectomy was observed. In 1972, the use of modified radical mastectomy (Madden-Auchincloss) without compromising the oncological outcome was published.

Next step was performing conservative surgery for breast cancer (lumpectomy with axillary lymph node dissection followed by radiation therapy to the breast). Oncological results of this technique were confirmed with the NSABP 06 study. Pioneers of this technique are Fisher in America and Veronesi in Italy. The National Institutes of Health Consensus Conference in 1991, affirm that: "the conservative treatment of the breast is an

* Corresponding Author's Email: mantonio.vaquero@salud.madrid.org.

appropriate method for breast cancer patients with stage I and II and is preferable because breast conserving further provides equivalent survival to mastectomy".

In 1992, Morton gave another step to a less radical approach to breast cancer with implementation of axillary sentinel node biopsy. Morton followed the hypothesis of Cabañas of sentinel node concept (1976), Cabañas affirmed that migration of tumor cells from the primary tumor targets a group of loco-regional lymph nodes (sentinel node) before spreading to the following lymph nodes areas, so if the sentinel node is free of tumor no other nodes would be affected. So if we confirm that axillary sentinel node is free of tumor, we could avoid axillary systematic lymphadenectomy. Selective sentinel node biopsy is now used routinely to stage the axilla.

In this chapter, we would perform a historical review from radical surgical techniques to lumpectomy and sentinel node biopsy and how surgeons have tried to evolve searching the best oncological results trying to offer also the best cosmesis to our patients.

HISTORICAL EVOLUTION OF BREAST CANCER CONSERVATIVE SURGERY

The surgical treatment of breast cancer has evolved dramatically since the early twentieth century, when techniques of radical resection were the norm. Today, it is accepted that breast cancer is a systemic disease, and so radical surgery does not offer longer survival than conservative surgery techniques. The aim of this chapter is to trace the evolution of breast cancer surgery over the past hundred years.

Halsted: From Radical Mastectomy to Modified Radical Mastectomy

During the first half of the twentieth century, Halsted radical mastectomy was the treatment of choice for breast cancer. This approach was supported by the mechanistic theory which considered breast cancer as a disease of loco-regional spread. The tumor was believed to disseminate gradually from its site of origin to the lymphatic vessels, then to regional lymph nodes, and finally to the bloodstream [1]. William Stewart Halsted (1852-1922), who subscribed to the theory of centrifugal spread, believed that local resection could cure cancer and that cancer recurrence seen in another location represented a new disease. In 1894 he described the technique of radical mastectomy, with which he managed to reduce the incidence of local recurrence from between 56-81% to 6%; unfortunately, 10-year survival was only 25%. The technique involves en bloc resection of the breast and of the major and minor pectoral muscles, and complete lymphadenectomy of the axilla and the supra- and infraclavicular fossa [2].

In the 1920s, Lane-Clayton carried out the first comparative studies of breast cancer survival, in relation to the surgical treatment performed. He observed that survival at three years was 29% after a non-radical mastectomy and improved to 43% after a radical mastectomy. Prognosis was related to the stage of disease at the time of surgery. This opinion was shared by Ewing, who found that survival was associated more with early diagnosis than with the surgical technique performed [3].

In the second half of the twentieth century, the improvements in health policy and medical care meant that breast cancers were diagnosed at earlier stages. In 1948, Patey and Dyson introduced a less aggressive form of mastectomy, called conservative radical mastectomy [4]. The Patey-Dyson technique preserved the pectoralis major muscle and achieved results for survival and local recurrence which were as good as those obtained with traditional mastectomy. In 1965, Madden and Auchincloss described the use of modified radical mastectomy with preservation of the major and minor pectoral muscles, without compromising the oncological outcome [5]. However, the first attempts at breast conservation are attributed to Mustakallio in Finland (1954), who proposed surgical tumor excision with free margins and adjuvant radiotherapy in patients with breast carcinoma without palpable lymph node, and obtained 5- and 10-year overall survival rates of 80.9% and 67.3% respectively [6]

In the 1950s and 1960s, less aggressive surgery for breast cancer gained growing support. It seemed reasonable to assume that tumor removal could be as effective as mastectomy. However, in 1978 Tagart et al [7] reported excessively high rates of local recurrence (37%) in stage I and II breast cancers three years after conservative surgery; therefore, modified mastectomy remained the standard of care.

Figure 1. Umberto Veronesi.

Fisher and Veronesi (Figure 1 and 2). In the 1980s, radical changes were introduced in the surgical management of breast cancer as a result of several factors.

The first of these factors was a change in the conception of the natural history of breast cancer. The mechanistic concept of illness was abandoned and breast cancer was now considered a systemic disease from the beginning. In this theory, first proposed by McDonald and reactivated by Fisher et al, tumor biology (cell kinetics, the host/ tumor relationship and degree of differentiation) determined the progression of the disease; this meant that regional lymph nodes were not a barrier against tumor progression, but an indicator of biological behavior [8].

Figure 2. Bernard Fisher.

This theory holds that tumor cells invade lymph nodes by embolization rather than by permeation, and that there is no ordered pattern of spread. Furthermore, the spread from the primary cancer occurs simultaneously via hematogenous and lymphatic pathways [8]. According to this new conception of the disease, the extent of local resection does not determine survival.

The second factor was the huge increase in the percentage of patients diagnosed with tumors less than 2 cm in size. This group now accounts for 30-50% of patients in industrialized countries. This is due to improved health education (media campaigns, assessment of the importance of early diagnosis and practice of breast self-examination), the application of non-selective screening programs including clinical, radiological and

laboratory tests, the development of better radiological techniques (mammography, ultrasound, xerography, thermography, breast CT), and the emergence of Breast Units [9].

The third factor was the confirmation that the survival rates achieved with conservative surgical treatment were similar to those obtained in the 1960s with more aggressive surgical and radiotherapeutic procedures [10]. Last but not least, the fourth factor was the active participation of patients in decisions regarding the treatment of their disease [10].

In 1973, Veronesi and colleagues began the first controlled clinical study at the Istituto Nazionale di Tumori in Milan, including 701 patients, which compared a group undergoing Halsted radical mastectomy versus another managed with an approach the authors termed QUART: lumpectomy (removal of the breast quadrant where the tumor is located) and axillary dissection and radiotherapy. They found no differences between the two groups regarding rates of overall survival (80% at 10 years) and achieved a 10-year local recurrence rate of 4.3% [11].

In the surgical technique described by Veronesi et al, quadrantectomy is defined by removing an entire breast quadrant including skin and fascia pectoralis. The breast nodule is identified and removed through a small skin incision, and sent to intraoperative study for histological confirmation. Once malignancy is confirmed, a lozenge incision is made whose major axis has a radial orientation relative to the nipple and the center is the scar made previously to perform the biopsy. En bloc exeresis, including skin, subcutaneous adipose tissue, mammary gland and the fascia of the *pectoralis major*, is performed. The mammary gland is then reconstructed in two planes (deep and superficial), with interrupted sutures of absorbable material, followed by suturing of the skin. The latter procedure requires special care, in view of the cosmetic purpose of conservative surgery [12].

Fisher et al published the results of the National Surgical Adjuvant Breast Project (NSABP), a multicenter controlled trial conducted at 34 hospitals in the US and Canada. In this study 1843 patients with stage I and II tumors up to 4 cm in diameter were randomly assigned to three groups: modified radical mastectomy, segmental mastectomy and axillary dissection without radiotherapy, and segmental mastectomy with axillary dissection and radiotherapy. At eight years, overall survival rates were similar for the three groups [13]. The results obtained with NSABP protocol confirm the role of conservative surgery plus radiotherapy for breast cancer [14].

Fisher et al describes lumpectomy as a tumor excision with 1-2 cm of surrounding healthy tissue. To achieve optimal aesthetic results these authors recommend using curved incisions rather than radial ones, and that these incisions must be located above the tumor. A small oval of the skin may be resected next to the underlying tumor to enable the pathologist to locate the anterior margin of the specimen, but skin resection does not increase the efficiency of the operation. The tumor is resected including the surrounding normal breast or adipose tissue and is immediately sent to the pathologist to confirm the diagnosis of cancer and to determine the macroscopic margin status. If the margin is positive, a re-resection is performed until a tumor-free margin is obtained. In the interests of improving the aesthetic results, it is not recommended to obliterate the "dead space" by bringing the breast tissue nearer, or to create thin skin flaps; nor are drains used. It is advisable to approximate subcutaneous fat with absorbable suture. The skin is closed with an intradermal suture [15].

At the Marseille Cancer Institute in France, between 1960 and 1981, Spitalier and Amalric treated more than 3,000 consecutive patients presenting operable infiltrating breast carcinoma with radiotherapy with or without primary limited surgery, which usually consisted

of local excision. Overall survival rates at 5, 10, 15 years were 85%, 75% and 55% respectively. They concluded that: "This conservative approach offers most women with operable breast cancer an excellent chance at breast preservation with the same chance for ten-year survival as with radical mastectomy" [16].

The National Institutes of Health Consensus Conference in 1990 stated that "Among their findings, the panel recommended that: (1) breast conservation treatment is an appropriate method of primary therapy for the majority of women with Stage I and II breast cancer and is preferable because it provides survival equivalent to total mastectomy and axillary dissection while preserving the breast; (2) the majority of patients with node negative breast cancer are cured by surgery or by surgery and radiation without further therapy; (3) there is clear evidence that rate of local and distant recurrence is decreased by both adjuvant combination cytotoxic chemotherapy and by adjuvant tamoxifen; (4) the decision to use adjuvant treatment should follow a thorough discussion with the patient regarding the possible risks and toxicities of therapy and its impact on quality of life; and (5) patients with tumors less than or equal to 1 centimeter have an excellent prognosis and do not require adjuvant therapy outside the clinical trials" [17].

After 20 years of follow up of previously cited randomized control trials, Veronesi's results confirmed that: "The rate of long-term survival among women who undergo breast-conserving surgery is the same as among women undergo a radical mastectomy. Therefore, conservative breast surgery is the treatment of choice for women with relatively small breast cancers" [18] and Fisher remarked that "lumpectomy followed by breast irradiation therapy remains appropriate for women with breast cancer, if margins of resected specimens are free of tumor and an acceptable aesthetic result can be obtained"[19].

According to the National Cancer Institute (Breast Cancer Database, 2007) conservative surgery is performed in more than 60% of patients with breast cancer, and conservative treatment should be considered the treatment of choice. It is indicated in all patients with a single, small tumor in the breast which can be excised with tumor-free margins, and achieves good cosmetic results. The patient must be able to receive postoperative external radiotherapy. If not all these conditions are met, mastectomy should be offered [20].

SENTINEL NODE LYMPHADENECTOMY (FIGURE 3)

Histological axillary node status is considered one of the most important prognostic factors. For many years, lymphadenectomy was crucial in the loco-regional surgical management of breast cancer.

In 1977, Ramón Cabañas established the concept of sentinel node (SN). Tumor cells migrate from the primary tumor to a group of loco-regional lymph nodes before spreading to the following lymph node "stations"; therefore, if the sentinel node is tumor-free, the other nodes will be tumor-free as well [21]. Based on Busch et al's studies of testicular lymphatic drainage with radiological contrast, Cabañas performed lymphangiography to locate the SN in patients with penile cancer. He established that this node was the first location of lymph node metastasis and may be the only one affected [22]. Therefore, he concluded that if the SN biopsy was negative, inguinal lymphadenectomy could be avoided.

In the 1980s, Morton et al applied the concept of SN to malignant melanoma by injecting dyes around the injury and subsequently inspecting the dyed lymphatic route and SN. Morton defined the concept of "intraoperative lymphatic mapping" and indicated the need for a learning curve of at least 30 patients to achieve good results [23]. In 1993, Alex and Krag [24, 25] used a gamma-ray probe after peritumoral injection of ^{99m}Tc -sulfur colloid to locate SN in patients with melanoma and breast cancer. In 1994 Giuliano used vital blue dye intraoperatively in the treatment of breast cancer [26], and Albertini combined the two methods in melanoma and breast cancer [27]. Turner validated the SN hypothesis [28] in a study of the first 103 patients with early breast cancer operated on by Giuliano. In these patients, the SN was located using dye, and subsequently lymphadenectomy was performed. The histopathological study of the SN was carried out staining with hematoxylin eosin (HE) and immunohistochemistry (IHC) was made using cytokeratins. In patients with disease-free SN, all non-sentinel lymph nodes were studied, finding metastases in only one. Turner concluded that if the GC is free from metastasis, the likelihood of disease in non-SN lymph nodes is $<0.1\%$. Therefore, identification of SN and histopathology study using HE and IHC techniques is a reliable indicator of axillary node status in patients with breast cancer.

Figure 3. Searching sentinel node with gamma probe.

Nowadays, selective sentinel node biopsy is the diagnostic technique of choice for axillary staging of breast cancer, since it avoids axillary lymphadenectomy. Being a less invasive technique, it is associated with lower rates of wound complication, as well as a lower risk of lymphedema and nerve involvement. It is indicated in all patients with breast cancer with clinically negative axilla, although it may be waived in cases in which the information on nodal status will not change the therapeutic decision [29]. Currently, most centers perform lymphadenectomy of Berg levels I and II in patients with positive sentinel node, though recently this practice has been questioned.

ONCOPLASTIC SURGERY

Conservative surgery of breast cancer has two objectives: local control of the disease, and a satisfactory cosmetic outcome. However, it is sometimes difficult to achieve both. The attempt to achieve adequate control of disease may require large resections that negatively affect the aesthetic results; alternatively, an attempt to improve the cosmetic results may mean that the resections made are too small and there is an increased risk of local relapse. Up to 30% of women operated on with conservative techniques present cosmetic defects such as breast asymmetry or deformity.

The word “oncoplastic” derives from the Greek: “onco” (tumor) and “plastic” (modeling). In 1998, the term was used by Werner Audretsch to define the concept of “tumor-specific immediate reconstruction” [30]. Its aim is to preserve the breast shape and contour, and symmetry with the healthy breast, by combining oncologic and reconstructive techniques. These techniques comprise four elements: a proper oncological technique for tumor removal and control, immediate remodeling of the defect, the re-placement of the nipple-areola complex (NAC) after remodeling, and correction of asymmetry in the contralateral breast [31]. Oncoplastic techniques have successfully expanded the indications for conservative surgery for bigger tumors.

CONCLUSION

In the twenty-first century, there is no doubt about the efficiency of breast conservative techniques. The management of the breast cancer patient should combine the best cancer treatment with minimal cosmetic damage. Breast cancer surgery should be individualized to each woman, to her tumor, and to her personal expectations.

ABSTRACT

Liver resection remains the only potentially curative treatment for primary and metastatic tumours of the liver. Nowadays, chemotherapy as the only treatment is not considered to be a curative option. In the past, suspected involvement of the hepatocaval confluence or inferior vena cava was long considered a contraindication for liver resection as a result of the risks for intraoperative air embolism or massive haemorrhage. The development of surgical technical innovations have made it possible to perform combined liver and inferior vena cava resections and expand the population of patients who may be considered for hepatic resection, and favourable clinical outcomes have been reported. However, the numbers of both related articles published and patients involved are limited so that it is difficult to provide sufficient evidence to draw a conclusion about the value of this procedure. Most of the data available consist of case reports or small series that emphasize the technical aspects of the procedures. In this chapter, a systematic review of the literature is performed to pool data from all individually documented patients to evaluate the safety and efficacy of combined liver and inferior vena cava resection in patients with colorrectal liver metastases involving inferior vena cava. Perioperative mortality rate is acceptable. The 5-year survival rate is also acceptable, given the lack of alternative nonsurgical curative therapies at present. Survival is comparable with corresponding survival data in previously described reports for such tumors. In the absence of prospective randomized studies, which are difficult to perform on the other hand, we can affirm the inferior vena cava resection is safe and feasible in high-volume centers with proven experience.

Keywords: colorectal liver metastases, inferior vena cava, liver resection, and hepatic resection

1. INTRODUCTION

Liver resection remains the only potentially curative treatment for primary and metastatic tumours of the liver. 5-year survival rates are reported to range from 30% to 50% after liver resection for metastatic colorectal cancer [1-4]. Nowadays, chemotherapy as the only treatment is not considered to be a curative option and, if left untreated, these patients usually have a median survival of considerably lower than 12 months [5].

In the past, patients with colorectal liver metastases involving the inferior vena cava (IVC) were considered poor candidates for surgical management and included few 5-year survivors. Suspected involvement of the hepatocaval confluence or IVC was long considered a contraindication for liver resection as a result of the risks for intraoperative air embolism or massive haemorrhage [6, 7].

The development of surgical technical innovations such as portal vein embolization, two-stage hepatectomies, re-do hepatectomies, total hepatic vascular exclusion (THVE), venovenous bypass, and ex vivo hepatic resection combined with new chemotherapy regimens have made it possible to perform combined liver and IVC resections and expand the population of patients who may be considered for hepatic resection, and favourable clinical outcomes have been reported [8, 9]. Liver resection in patients with IVC involvement is becoming more common with the adoption of these techniques and, when necessary, with the replacement of the IVC using several materials [10-13].

However, the number of both related articles published and patients involved are limited so that it is difficult to provide sufficient evidence to draw a conclusion about the value of this procedure. Most of the data available consist of case reports or small series that emphasize the technical aspects of the procedures [14-23]. The longterm outcomes and oncological integrity of such procedures remain unclear.

In this chapter, a systematic review of the literature is performed to pool data from all individually documented patients to evaluate the safety and efficacy of combined liver and IVC resection in patients with colorectal liver metastases involving IVC.

2. METHODS

This study was performed by following the recommendations of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) Statement [24]. The level of evidence of each study was classified according to the Oxford Centre for Evidence-Based Medicine levels of evidence [25].

2.1. Literature Review

A systematic literature search was conducted using PubMed, Embase and the Cochrane Library, to identify articles published from January 1980 to July 2018. Search terms were: “colorectal liver metastases,” “inferior vena cava,” “liver resection,” and “hepatic resection.” Bibliographies of the retrieved studies were checked manually for additional studies.

2.2. Inclusion Criteria

a) Papers presenting data on combined liver and IVC resection for colorectal metastases; b) original data published; c) long-term outcomes available.

2.3. Exclusion Criteria

a) Non-English language studies; b) papers without original data; c) animal studies; d) the absence of individual patient data; e) IVC resection for any type of tumor other than colorectal cancer metastasis, and f) the absence of longterm data.

Three authors independently reviewed all the retrieved studies that met the inclusion and exclusion criteria. Discrepancies between the three authors were resolved by discussion and consensus.

The following data were collected for each patient: age, sex, number of resected metastases, type of hepatic resection, type of vascular control, type of reconstruction of the IVC, morbidity, mortality, 3 and 5-years survival, mean follow up, and disease-free survival. As the IVC resection is still a rare type of surgery, in several studies there are series of this type of surgeries for different tumors as cholangiocarcinoma, hepatocellular carcinoma, or renal or adrenal tumors with IVC infiltration. Sometimes it is difficult to extrapolate data from patients operated only for colorectal liver metastases. A descriptive analysis of all the data collected is shown.

3. RESULTS

3.1. Characteristics of the Study Population

Search of the literature yielded 73 articles (Figure 1). After screening, a total of 151 patients were described in 16 articles eligible for inclusion [26-41]. All these studies were observational in nature and classified as level-4 evidence. The characteristics of the studies populations are outlined in Table 1.

Figure 1. Flowchart of study selection.

3.2. Surgical Outcomes

A total of 151 patients with resection of liver metastases and ICV were included. The mean age was 58 years (range 35-84 years). We included 66 men and 53 women (2 studies did not include the sex of the patients). The mean number of resected metastases was 2.2 (range 1-27). The most frequent hepatic resections were: 36 right hepatectomies, 21 right trisectionectomies, 21 segmentectomies, 10 left hepatectomies, 8 extended right hepatectomies, 7 extended left hepatectomies, 6 left trisectionectomies, and 3 wedge resections. In 3 cases diaphragm was resected, in 3 the right adrenal gland and in 1 the right kidney. The most performed types of vascular control were: THVE in 63 cases, lateral clamping in 42 cases, total vascular exclusion with hepatic hypothermic perfusion in 6 cases, partial vascular exclusion in 3 cases, intermittent pedicular clamping in 4 cases, and IVC clamping in 2 cases (in 2 papers, it was not possible to extrapolate the type of clamping because was not specified according to the type of tumor). Postoperative morbidity was 45.6%, and mortality was 4.5%. Survival at 3 and 5 years was 55.6% and 32%, respectively. The mean follow-up was 22.7 months and the median disease-free time was 10.5 months. No conclusive data can be extracted from the average survival in these subgroup patients in the studies shown.

4. DISCUSSION

Hepatic malignancies involving the IVC are generally associated with poor clinical outcomes. The principles of curative-intent surgical oncology demand an en-bloc resection of organs potentially invaded by cancer. Limited availability of organs and poor survival resulting from the high rate of tumor relapse after liver transplantation for advanced hepatic malignancies with macroscopic vascular invasion have made liver transplantation unsuitable for these types of malignancies. Since the first description of combined liver and IVC resection by Starzl in 1980 [19], an increasing number of papers have been published in recent years, but robust evaluation of the literature is limited. All these studies are single patient reports or series including only a small number of patients [26-41], and the majority are studies that include IVC resections for different types of tumor, with analysis of the results together, without being able to extract reliable results in the subgroup of patients with hepatic metastases of colorectal cancer. The present study is based on individual patient data and includes the largest number of patients who underwent combined liver and IVC resection for colorectal liver metastases, thus providing clear evidence to support this surgical approach as a safe and effective intervention for liver metastases involving the IVC. Considering the technical complexity of combined liver and IVC resection as compared with standard liver resection, the perioperative mortality rate of 4.5% is acceptable. Long-term survival is the most conclusive parameter in the assessment of therapeutic strategies for malignant tumors. The 32% 5-year survival rate is also acceptable, given the lack of alternative nonsurgical curative therapies at present. Survival is comparable with corresponding survival data in previously described reports for such tumors [42, 43].

Histopathological examination of the resected specimens in different papers showed that almost 40% of hepatic malignancies with suspected IVC involvement had only fibrous adhesion without true tumor invasion. Precise distinction between vascular invasion and inflammatory adhesions is difficult by preoperative imaging modalities or intraoperative exploration. Malde *et al.* [35] proposed that the surgeon should endeavor to peel the tumor from the IVC as this is possible more often than not. However, such procedure may cause tumor rupture, massive bleeding and dissemination of tumor cells. In addition, it is almost impossible to dissect from the IVC wall without producing a caval vein defect even in the setting of inflammatory adhesions. More importantly, data showed that long-term survival of patients with true invasion of the IVC was comparable to that of patients without vascular invasion, indicating that true invasion of the IVC per se is not a surrogate of aggressive tumor biology; rather it is a reflection of tumor location.

The vascular control was adapted in all the cases during surgery with the aims of minimizing the need for transfusion, shortening the ischaemia time of the remaining liver, maintaining stable systemic haemodynamics, and improving the tolerance of the remnant liver to ischaemia-reperfusion injury.

Several types of vascular control were used in this series. The first of these was hemiliver clamping, whereby no clamping was applied to the remaining liver and the clamp time was considered to be zero. Similarly, when only the portal vein or the hepatic artery was clamped, maintaining the flow of the other vessel (the artery or the portal vein respectively), the clamp time was considered to be zero as well. The second option was intermittent Pringle manouver, consisting of alternating periods of clamping of 15 min for and 5 min declamping, repeated

until the end of the hepatectomy; the total clamp time was taken as the sum of the periods of clamping. Third, vascular exclusion without caval clamping (preserving retrohepatic caval flow) was used for liver tumours compressing or involving at least one of the three main hepatic veins away from their roots at the vena cava. Resection was then performed via an anterior approach in most of the patients. Finally, standard THVE of the liver was used for tumours of the hepatocaval confluence. This method involved mobilization of the liver and isolation of the suprahepatic and infrahepatic vena cava and the hilum. A venovenous bypass was used in the event of haemodynamic intolerance to caval clamping. Vascular resections were carried out only when the vessels could not be freed safely from the tumour, irrespective of the preoperative plan [35-37].

Reconstruction of the IVC depends on the extent of IVC involvement. In general, direct suture of the IVC is indicated if a <2 cm wall is excised without involving the major hepatic veins. A patch or a synthetic/autologous graft can be used in the presence of extended infiltration of the wall (>2 cm) to prevent lumen stenosis. Finally, in patients with infiltration of at least one half of the IVC circumference, total replacement of the IVC with a vascular conduit is often required [35]. Although the autogenous or homologous vein is the preferred material for venous replacement due to its nonthrombogenic and infection-resistant advantages, it may not be technically feasible, particularly if a relatively long segment of the IVC is to be replaced. Thus, reconstructions using synthetic grafts are most frequently performed. A major concern with the use of synthetic grafts is infection, however, which was not documented in any patients included in current analysis of the literature. In patients where tumor involvement of the IVC is small, control of the IVC can be achieved simply by placing the vascular clamps tangential to the vena cava to preserve the IVC flow.

In patients where tumor involvement requires resection of a greater portion of the IVC, THVE including continuous clamping of the portal triad and the suprahepatic and infrahepatic IVC with or without veno-venous bypass is the standard technique. If involvement of the IVC is below the level of the hepatic veins and there is sufficient room to place a vascular clamp above the tumor but below the hepatic veins, caval occlusion should be performed below the hepatic vein after hepatic transection to maintain perfusion of the liver and minimize the hepatic ischemic time [38]. If extensive involvement of the IVC at the hepatic vein confluence exists, ex situ hypothermic liver resection is indicated. However, this technique is associated with a significant mortality rate, as high as 28%, with some patients needing salvage liver transplantation [44]. An alternative technique is the ante situm procedure, which was first introduced by Hannoun *et al.* in 1991 [45]. In this technique, after completely dividing the liver together with the IVC from the retroperitoneum, the liver can be anteriorly mobilized out of the abdomen. Then, the liver is perfused with a cold preservation solution via portal vein and the parenchymal resection is performed. After completion of the parenchymal resection, the IVC and venous outflow reconstruction is performed with or without the use of grafts. The major advantage of the ante situm procedure over an ex situ resection is the preservation of the hepatic pedicle without division, which can reduce the morbidity and mortality significantly [44]. Given the extensive nature of the ante situm procedure, it is usually performed in highly selected patients in experienced high-volume hepatobiliary centers.

This present analysis has several limitations. First, all of the included studies were retrospective with an inherent risk of bias. Differences in some variables including the institution's experience, perioperative management, study populations, surgical procedures,

IVC resections, and reconstructions may have influenced survival results. Secondly, the favorable survival rate achieved with combined resection of the liver and IVC could be due in part to the highly selected patients who may have had a good prognosis. Third, considering the included studies over three decades, it is important to consider that outcomes may have been influenced by the era in which the surgery was performed. Fourth, the survival of patients with hepatic metastases from colorectal cancer has increased in recent decades not only because of technically more aggressive surgeries, but also because of the development of new lines of chemotherapy that allow a better control of the disease. In fact, in most studies, the percentage of patients receiving adjuvant chemotherapy is greater than 50%, in some cases even reaching 80% [37].

CONCLUSION

Despite the difficulty of resection of the IVC, in recent decades there have been numerous technical advances that allow the increasing resection of patients with liver metastases of colorectal cancer involving IVC. The studies published so far are retrospective and many of them include resection of IVC for tumors other than colorectal liver metastases. However, published perioperative morbidity and mortality are comparable to the data published for this type of tumor without involvement of IVC. In the absence of prospective randomized studies, which are difficult to perform, we can affirm the IVC resection is safe and feasible in high-volume centers with proven experience.

ABSTRACT

The disorder of sex development (DSD) is defined as the congenital conditions in which the development of the chromosomal, gonadal, or anatomical sex is atypical. Congenital adrenal hyperplasia (CAH) consists of a family of disorders caused by reduced activity of enzymes required for the biosynthesis of cortisol in the adrenal cortex, resulting in increased levels of dehydroepiandrosterone sulfate and testosterone. The masculinization of a DSD 46XX patient with CAH is caused by excessive levels of male hormones. During adolescence, the diagnosis of DSD is often an alarming and traumatic event for both the adolescent and the family, considering that this a rare disorder and absolutely foreign to the majority of non-medical individuals. The management of DSD is extraordinarily heterogeneous across centers, and pre- and post-treatment evaluations are mostly subjective, examiner-dependent, and influenced by cultural norms.

* Corresponding Author's E-mail: kanadisuma@yahoo.com.

In this article, we report a rare case of delayed diagnosis of DSD 46XX in a 23-year-old patient with CAH. The patient exhibiting genital ambiguity and primary amenorrhea, desired to be a male person. The levels of hormones were as follows: high dehydroepiandrosterone sulfate, 937.8µg/dL; high testosterone, 27.3nmL/L; and low estradiol, 45pg/mL, corresponding to the normal levels of a male. A multidisciplinary team, consisting of a reproductive endocrinologist, plastic surgeon, metabolic endocrinologist, psychiatrist, and the hospital ethics committee, collaborated to address the patient's desire regarding her gender condition. Prolonged exposure to androgens results in masculinization of the brain.

Therefore, she preferred to become a male instead of a female. She underwent total laparoscopy hysterectomy and masculinizing reconstructive surgery on her external genitalia.

In addition, prior to and following surgery, the patient received psycho-adaptive therapy.

Keywords: disorder of sex development 46XX, congenital adrenal hyperplasia, gender reassignment surgery, multidisciplinary approach

INTRODUCTION

The disorder of sex development (DSD) is defined as congenital conditions in which the development of the chromosomal, gonadal, or anatomical sex is atypical. This broad category is divided into three primary groups based on karyotype, namely 46XY; 46XX, and sex chromosome DSD. Secondary groups are formed based on hormonal assessment and imaging [1, 2].

Congenital adrenal hyperplasia (CAH) consists of a family of disorders caused by reduced activity of enzymes required for the biosynthesis of cortisol in the adrenal cortex. The most common defect is 21-hydroxylase (21-OH) deficiency, occurring in 90% of all cases [3]. The disorder appears to be more common in individuals of Hispanic, Slavic, Italian, and European Jewish ancestry. The incidence of genital ambiguity is 1 per 4,500 individuals, though some degree of male under-virilization or female virilization may be present in 2% of live births [4]. In Indonesia, only a limited number of hospitals have a team dedicated for the management of DSD. Thus, currently, data related to DSD remains scarce.

Typically, the management of a DSD patient with CAH depends on the time of diagnosis. In cases in whom CAH is recognized immediately after birth, medical treatment is the treatment of choice. However, in those diagnosed at a later stage of life, it has been suggested to offer the following option to the patients/family: raise the child as a male, postpone the surgery, and suppress puberty until a definitive choice is reached by the patient. Genital surgery continues to be controversial regarding its indications, timing, and technical aspects [5].

During adolescence years, the diagnosis of DSD is often an alarming and traumatic event both for the adolescent and the family, considering that this is a rare disorder and absolutely foreign to the majority of non-medical individuals [6]. The goal of gender reassignment is to improve the quality of life of the patient. The development of the reproductive system, sexual identity, sexual function, and fertility are important factors to be considered in this process [7]. The management of DSD is extraordinarily heterogeneous across centers, and pre- and

post-treatment evaluations are mostly subjective, examiner-dependent, and influenced by cultural norms [5].

In this article, we report a rare case of delayed diagnosis of DSD 46XX in a patient with CAH. A multidisciplinary approach was used to address the gender condition of this patient.

CASE REPORT

A 23-year-old patient was referred to our hospital from the Public Hospital in Riau Province due to DSD 46XX. She was delivered by a traditional birth attendant. Initially she was pointed out as a female. During her childhood, she was nurtured as a female.

However, after the age of 12 years, her behavior changed dramatically. She began to identify herself as a male individual. Furthermore, her genitals did not resemble those of a normal female. Since she was unable to accept the response from the surrounding, she finally decided to discontinue her education. Initially, her parents recognized a discrepancy in the appearance of her genitals. Unfortunately, they did not have sufficient information to explain the phenomenon, and considered it to be a normal variation. In 2012, the patient was examined by a local urologist and was referred to the Dr. Cipto Mangunkusumo Tertiary Hospital, Jakarta, Indonesia. Unfortunately, her parents postponed this plan due to financial challenges.

The patient is the youngest in a family of seven children who live with their parents. Daily activities include assisting her parents with their work. She performs household chores similar to a male person (i.e., lifts the bucket, fixes the electricity, and paints the wall). Sometimes she is confused regarding her gender, sex, and social identity. Currently, individuals who live in the surrounding call her “Ucok” (a nickname for a young boy). Lately, she began to be attracted to a female, but was unsure how to express her feelings to a woman.

The patient has not experienced menstruation or breast development, and did not report a history of cyclic lower abdominal pain. However, she demonstrates growth of pubic and axillary hair.

Following physical examination, she appeared in good condition and hemodynamically stable. The body mass index of the patient was 27.30kg/m² (i.e., overweight), while the body height and weight were 148cm and 60kg, respectively. The general status was within normal limits (i.e., no galactorrhea, the Ferriman Galleway score was >7, and the Tanner stage was M1P4).

Gynecological evaluation revealed ambiguous genitalia (i.e., a vagina and phallus of 5cm were observed, without scrotum). Rectovaginal touch showed non-palpable uterus and adnexal mass.

Transrectal ultrasound was performed, and the results were as follows: uterine size 29 × 16 × 26mm, volume 6.72mL, and endometrium 3.7mm, with a regular basal layer.

Both ovaries were small (volume of right and left ovaries: 1.32mL and 0.62mL, respectively) with a total number of follicles <6. Computed tomography, previously performed at a different hospital, confirmed the presence of a uterus and absence of testes.

Figure 1. 1) M1 of breast maturity, 2–4 and 7) Ferriman Galleway score >7, 5) male appearance and short stature, 6 and 7) genital ambiguity.

Figure 2. Transrectal ultrasound shows: 1) small uterine size, 2) and 3) small ovaries.

The results of the chromosomal analysis revealed DSD 46XX. Laboratory findings were as follows: normal morning cortisol 8.8µg/dL (normal range, 3.7 – 19.4µg/mL), high dehydroepiandrosterone sulfate (DHEAS) 937.8µg/dL (normal range, 134.2 – 407.4µg/dL), normal anti-mullerian hormone 2.32ng/mL (normal range, 0 – 14.8ng/mL), high testosterone 27.3nmol/L (normal range for male, 4.94 – 32nmol/L), low luteinizing hormone <0.5mIU/mL (normal range for male, 0.57 – 12.07mIU/L), follicle stimulating hormone 2.62mIU/mL (normal range for male, 0.95 – 11.95mIU/mL), estradiol 45pg/mL (normal range for male, 11 – 44pg/mL). The glucose profile was normal in terms of fasting blood glucose, and 1h and 2h glucose tolerance test (89mg/dL, 183mg/dL, and 148mg/dL, respectively). Kidney function was normal in terms of urea and creatinine. The levels of electrolytes were also within normal limits (sodium 138mEq/L, potassium 4.3mEq/L, and chlorine 101.3mEq/L).

The patient was diagnosed with primary amenorrhea, DSD 46XX, ambiguous genitalia, and CAH. A multidisciplinary team, consisting of a reproductive endocrinologist, plastic

surgeon, metabolic endocrinologist, psychiatrist, and the ethics committee of the hospital, was formed. An immediate consultation was arranged to assess the case based on every discipline involved in the team.

Examination using abdominal ultrasound did not detect the presence of an adrenal tumor or abnormalities in the abdominal organs. No specific therapy from Metabolic-Endocrine of Internal Medicine. The patient was evaluated by a psychiatrist and diagnosed as follows: axis I, mood adaptation disturbance; axis II, avoidance of personality; axis III, DSD 46XX; axis IV, this medical condition; axis V: current Global Assessment of Functioning score was 80 and the highest level past year was 85. Supportive psychotherapy and psychoeducation for the patient and her family were planned. The plastic surgeon concurred with the initial diagnosis, and planned to perform reconstructive surgery (i.e., radial free forearm flap and implant to enlarge the phallus) to support the gender preference of the patient.

According to a meeting of the multidisciplinary team, the patient identified (i.e., self and gender concept) with the male gender. For preparatory purposes related to the reconstructive surgery, the plastic surgeon reexamined her external genitalia during erection. Considering that the level of testosterone at the time of consultation was already sufficiently high to support her gender identity, the reproductive endocrinologist decided not to administer hormonal support. A member of the ethics committee proposed that the gender reassignment should also proceed legally after the surgery.

She underwent total laparoscopic hysterectomy, performed by a reproductive endocrinologist. The management was continued with the release of cordae and urethroplasty, performed by a plastic surgeon. The decision regarding the hysterectomy was reached based on the patient's request.

Figure 3. Abdominal ultrasound: Absence of a suprarenal mass.

Figure 4. External genitalia in erection condition: 1) penile shaft 4–5 cm, 2) erection position, and 3) cordae.

Figure 5. 1 and 2) total laparoscopic hysterectomy, 3) uterus specimen.

Figure 6. Release of cordae and urethroplasty (step 1), performed by a plastic surgeon.

The psychiatrist administered anti-depressant agents and psycho-supportive therapy. Moreover, the plastic surgeon planned to perform a second procedure (i.e., reconstruction surgery to form the scrotum and phallus) 6 months later.

DISCUSSION

In patients with DSD 46XX, classic CAH represents the most common diagnosis. Usually, there are no gender issues in this group of patients, except in cases of late diagnosis and severe masculinization [5]. In the present case, gender was the main issue due to the delayed diagnosis. The lack of knowledge by the parents and traditional birth attendant regarding genital ambiguity, the minimal information regarding DSD among the community, and financial challenges contributed to this delay. In settings of limited resources, especially in the absence of neonatal screening, examination of the genitalia is crucial for the detection of CAH. Virilization of the external genitalia without palpable gonads should arouse suspicion of CAH, and is an indication for the urgent referral of the patient to an endocrine specialist [8].

Genital ambiguity can be caused by high exposure to androgens in a 46XX individual, or under-masculinization in a 46XY individual. In 46XX genital ambiguity, the source of high exposure to androgen may be external or internal. Internally, there are two organs responsible for the production of androgens, namely the ovary and adrenal gland [5, 6].

CAH results in increased production of androgens from the adrenal gland due to an enzyme deficiency. The most common defect in CAH is 21-OH deficiency, caused by mutations in the cytochrome CYP21A2 gene. This leads to failure in the synthesis of cortisol due to the impaired conversion of 17α -hydroxyprogesterone to 11-deoxycortisol [9]. Clinical

consequences of 21-OH deficiency arise primarily from the overproduction and accumulation of precursors proximal to the blocked enzymatic step. These precursors are shunted into the androgen biosynthesis pathway and further converted to testosterone and dihydrotestosterone [3, 10]. These hormones affect multiple somatic systems that may have psychological implications, including glucose household (at any ages), differentiation of the reproductive tract and presumably the brain (during prenatal development), and growth of primary sex characteristics, development of secondary sex characteristics, further differentiation of the brain, and activation of previously organized brain circuits (during puberty) [11].

Masculinization of patients is observed since childhood. The brain organization theory suggests that, during fetal development, steroid hormones permanently organize the brain in terms of gender, including patterns of sexuality, cognition, temperament, interests, and mental health that are considered “masculine” or “feminine” [12]. In DSD 46XX patients with CAH, prenatal exposure to androgens (the high prenatal levels of male sex hormones to which the genetically female brain is exposed) may shift some, but not all, personality characteristics in the male-typical direction in females [8, 10, 11].

The three components of sexual psychosexual development (i.e., gender identity, gender role, and sexual orientation) may not always be concordant and aligned in individuals with DSD. However, in those with DSD, the primary goal is for gender identity to be consistent with gender assignment [7]. In cases of late diagnosis, it has been suggested to offer the option of raising the child as a boy, and postpone surgery until a definitive choice is reached by the individual. The majority of DSD 46XX patients with CAH are raised as males (usually with a marked degree of genital masculinization) and do not develop gender dysphoria. The cultural environment of the child is of utmost importance in this decision process [5].

As suggested by different studies, the multidisciplinary approach should be established for the management of DSD cases [4]. Such a multidisciplinary team consists of a reproductive endocrinologist, plastic surgeon, psychiatrist, urologist, and ethic-medicolegal consultant. This approach satisfies the requirement to assess and manage DSD patients from different medical perspectives, prior to reaching a consensus based on the preferences of the individual.

As the child develops and reaches adolescence, the gynecologist is again uniquely positioned to assist the family with discussions regarding sexuality and reproductive issues. In addition, many of these conditions are not diagnosed until adolescence when lack of menstruation, pubertal development, or virilization elicits a referral to the gynecologist. Thus, the first physician to diagnose many of these conditions during adolescence may be the gynecologist [2]. The initial evaluation involves assessment of the patient’s medical history of familial disorders, a physical examination with particular attention to the genitalia, determination of the karyotype, and (if findings are consistent with CAH) a rapid evaluation of 17-hydroxyprogesterone. However, in Indonesia, finding a laboratory which provides an evaluation of the level of 17-hydroxyprogesterone is challenging. Therefore, initially, the level of total testosterone should be measured to confirm the increased presence of androgens. In cases with high levels of total testosterone, the primary source of androgens should be determined either in the ovary or the adrenal gland by measuring the DHEAS. A high level of DHEAS indicates that the primary source of androgens is the adrenal gland.

Gender is determined by the chromosome, social environment, social role, and sexual orientation. Although the chromosome of this patient was 46XX, the patient’s gender identity tended to develop as a male individuals based on the social role, social environment, and

sexual orientation [11, 13]. It is truly a great challenge to deal with gender issues in DSD cases. Such research lays the groundwork for additional investigation regarding the contribution of genetic risk, pubertal timing, and sociocultural experience of gender to neural changes underlying mood and anxiety symptoms [14]. Mood conditions, especially depression, anxiety and affective distress, are frequently reported in males and females with CAH. Such conditions may be traced to imbalances of steroid hormones, including cortisol, and the cortisol precursors adrenocorticotrophic hormone and corticotropin releasing hormone, a neurotransmitter centrally involved in endocrine, autonomic, immune, and behavioral responses to stress [12]. Psychiatric treatment includes the use of psychopharmacologic agents and supportive psychotherapy techniques [13].

The aims of surgery in DSD patients are as follows: to restore functional genital anatomy allowing future penetrative intercourse (as a male or a female), facilitate future reproduction (as a male or a female) when possible, and reduce urological hazards related to abnormal genitourinary anatomy [5]. For the reconstruction of the genital tubercle in males, surgery is based on the principles of hypospadias surgery, which involves three main steps: (1) degloving of the genital tubercle to assess the severity of the hypospadias based on the level of division of the corpus spongiosum, the degree of hypoplasia of the ventral tissues and the subsequent ventral curvature, the position of the urethral meatus, the length of the urethra to be reconstructed, the size of the genital tubercle, the size and shape of the glans, and the availability of foreskin tissue; (2) refashioning of the missing urethra (i.e., urethroplasty), and (3) refashioning of the penile skin shaft [5].

Although the relevant legislation varies between countries, it is usually allowed to delay a child's gender registration until the medical situation is clarified. Genital surgery continues to be controversial regarding its indications and ethical aspects. The management is extraordinarily heterogeneous across centers, and pre- and post-treatment evaluations are mostly subjective, examiner-dependent, and influenced by cultural norms [5]. The ethical-medicolegal aspect was included in this multidisciplinary team to support the family in processing the legal aspect of gender registration in this patient.

It is important to note that the formation of a multidisciplinary team is more than bringing together different specialists. These specialists create a process for clinical care and decision-making. This process is continuously evaluated and adjusted to optimally serve the patients and the community. It is important that the members of the team communicate with each other on a regular basis to ensure optimal care for the patient and family. Currently, there are many areas for which there are no clear guidelines regarding management. In such cases, the team must reach decisions together with the patient and parents, taking into account a variety of factors (i.e., genetic, endocrine, and anatomic findings) along with the preferences of the individual and the values of the family. Among these decisions, gender reassignment and surgical management are among the most difficult. Thus, communication between the team members regarding their unique perspective, based on their field of expertise, is essential. It has been noted that parents reach different decisions depending on the individual who counsels them regarding surgery. Therefore, it is important for the team members to communicate with the families regarding their different perspectives in an open and caring manner. In addition, the members of the team can discuss all pertinent medical and psychosocial issues prior to the consultation with the family (to ensure a clear understanding of the medical condition), as well as after the consultation (to reach a consensus regarding management) [2].

CONCLUSION

DSD is a clinical condition which requires attention from a clinical perspective, as well as beyond the clinic. Lack of knowledge may significantly contribute to a delayed diagnosis. DSD is a condition that should be managed individually, based on the main needs and values of the patients and their families. Masculinization of the brain and genitalia in patients with delayed diagnosis of DSD 46XX requires a multidisciplinary approach. Raising awareness and advancing knowledge related to genital ambiguity is crucial for the prevention of delayed diagnosis.

CEREBROVASCULAR BYPASS SURGERY IN THE TREATMENT OF BRAIN ANEURYSMS

Goran Mrak, Jakob Nemir*, MD, PhD and Hrvoje Barić

Department of Neurosurgery, Clinical Hospital Center Zagreb,
Zagreb University Medical School, Zagreb, Croatia

ABSTRACT

Background: Nontraumatic subarachnoid hemorrhage (SAH) occurs secondary to a ruptured brain aneurysm or an arteriovenous malformation (AVM) or, rarely, the underlying etiology remains uncertain. The vast majority of aneurysm cases are treated by open surgery (clipping), using the endovascular approach (coiling), or a combination of both. However, complex aneurysms, such as giant and fusiform aneurysms, are not amenable to treatment using the conventional techniques. Rather, in such cases a cerebrovascular bypass procedure is used to enable sacrifice of the parental vessel and preserve distal blood flow. Different techniques and approaches have been described in the literature for various types of aneurysms. Given the relative scarcity of cases and technical differences between neurovascular centers, defining robust diagnostic criteria, indications, surgical techniques and outcome measures to assess efficacy and safety, remains a challenge.

Aim: The aim of this chapter is to provide a summary of techniques and indications related to cerebrovascular bypass surgery for aneurysmal SAH cases and to provide a review of published series.

Methods: First, a historical perspective is outlined, followed by preoperative assessment, summary of techniques, postoperative evaluation, and complications associated with the procedure. A review of the literature is reported next: relevant electronic databases and scholarly journal archives were searched, ending March 2019, and complemented by a hand-search of lists of references, to identify publications which: i) described a surgical revascularization technique; ii) reported patients are brain aneurysm cases (with or without SAH); iii) reported safety and efficacy outcomes; iv) were published in English or German; and v) were published in a peer-reviewed journal. Two illustrative cases operated at our Department are presented at the end.

* Corresponding Author's Email: jakob.nemir@kbc-zagreb.hr.

Conclusion: Despite its technical challenges and lack of data from clinical trials, cerebral revascularization procedures should be further developed by neurosurgeons, as they remain the only option of treatment for a significant number of patients.

HISTORICAL PERSPECTIVE

The Ebers Papyrus, dating back to 3000 BC, contains what is considered the first description of cerebrovascular anatomy. Among the ailments and remedies reported in the Papyrus is the case of a brain aneurysm treated by a “fireglazed instrument” (Lippi 1990, Engelhardt 2017)). The influence of ancient Greek medical practices had a profound impact on the overall medical sciences, including surgery. Hippocrates (460-370 BC) was the first to recognize the clinical syndrome of sudden onset headache and co-occurring neural deficits - the “apoplexy” - and, what is more, he realized it to be a direct consequence of a cerebrovascular event. Herophilus of Chalcedon (335–280 BC), the “father of anatomy” is credited with the first description of the circulatory system, including the “wonderful net” (lat. *rete mirabile*) of the brain vessels and the confluence of dural sinuses, the *torcular herophili* (Soldozy et al. 2019). Galen of Pergamon (AD 129–199) further enriched the anatomical corpus and coined the term “aneurysm” (Polevaya et al. 2006). In the Dark Ages that followed, Western medical knowledge largely remained dormant as dissections were banned by the religious authorities. During the period that spanned 1500 years, advances were made by Islamic scholars, most notable of which are Rhazes (865–925) and Avicenna (980–1037). However, it was not until the 16th century that the Galenic anatomical dogmas were challenged and corrected by Andreas Vesalius in his revolutionary 1543 *De humani corporis fabrica* (Lo and Ellis 2010). Over a century later, a major breakthrough in the understanding of anatomy and physiology of the brain circulation occurred, when in 1684 Thomas Willis described the bypass properties of the cerebral vascular supply.

Despite these anatomical advancements, the guiding philosophy in treatment of vascular pathology remained unchanged for hundreds of years - the aim of treatment was to exclude the impaired vessel from the circulation. Until the early 19th century the main treatment option was cauterization, which was then replaced by the technique popularized by John Hunter, who showed that peripheral arteries could be safely and efficiently ligated (Cooper 1837). This technique was introduced into the neurosurgical armamentarium by Victor Horsley, who, in 1885, ligated the internal carotid artery of a patient suffering from an aneurysm encountered after craniotomy for removal of a presumed middle fossa tumor (Drake 1985). A quarter of century later, Alexis Carell developed the triangulation suturing technique which enabled the means to achieve vessel anastomosis and was the first to describe venous patch grafts (Rickard and Hudson 2014). In the meanwhile, proximal ligation remained the primary treatment option for aneurysms and was used by the great Harvey Cushing himself, in spite of its unpredictable outcomes (Polevaya et al. 2006). Interestingly, Cushing invented the first surgical clip to place on inaccessible vessels during tumor resections. However, he did not use the device to clip an aneurysm – the first surgeon to use this device in this indication was Walter Dandy in 1937. In the years that followed, the field witnessed technical refinements in surgical instruments and advancements in understanding of properties of cerebral blood flow, but two achievements completed the setting from which

modern neurovascular surgical procedures would evolve – angiography by Egas Moniz in 1927, and use of the operating microscope in neurosurgery in 1957 (Kurze 1964).

In 1967, Mahmut Gazi Yaşargil performed the first extracranial-intracranial (EC-IC) bypass (superficial temporal artery – middle cerebral artery (STA-MCA)) on a patient with occlusion of the MCA (Vilela and Newell 2008). In 1972, he performed the first EC-IC bypass for moyamoya disease and was the first to report the use of a EC-IC bypass in the management of an aneurysm (Thanapal et al. 2018, Spetzler, Schuster and Roski 1980). In 1971 Loughheed performed a EC-IC bypass using a venous graft, in 1974 Spetzler described the use of the occipital artery for the EC-IC bypass, and in 1978 Ausman anastomized the vertebral artery (VA) to the posterior inferior cerebellar artery (PICA) using a radial artery (RA) graft (Soldozy et al. 2019). Other innovative techniques in the field were subsequently reported and are today considered standard (Tamargo 2008).

To evaluate efficacy and safety of the possibilities that the EC-IC bypass procedure provided, three landmark studies were performed. First was the 1977-1985 EC/IC bypass study to investigate the procedure in symptomatic carotid artery occlusion and it failed to show benefits of the procedure. Second was the 2002-2010 Carotid Occlusion Surgery Study (COSS) which was terminated early for futility and showed that EC-IC bypass plus medical therapy was not superior to medical therapy alone in reducing the risk of recurrent ipsilateral ischemic stroke in patients with symptomatic atherosclerotic internal carotid artery occlusion (AICAO) and hemodynamic cerebral ischemia (The EC/IC Bypass Study Group 1985, Powers et al. 2011). Finally, the 2001-2013 Japan Adult Moyamoya (JAM) trial showed that bilateral EC-IC bypass surgery was superior to conservative care in preventing rebleeding at five years in patients with hemorrhagic moyamoya disease (Miyamoto et al. 2014).

Owing to the results of the mentioned studies, as well as advances in medical treatment and renaissance of endovascular techniques, the indications for the EC-IC bypass have narrowed and the numbers of patients undergoing the procedure declined. Nevertheless, it remains the primary treatment option for certain groups of patients (Mrak et al. 2018).

INDICATIONS

Despite the lack of robust evidence, the EC-IC bypass continues to be used in the treatment of complex intracranial aneurysms not treatable by endovascular coiling or surgical clipping, skull base tumors encasing arteries, moyamoya disease, and vascular occlusive disease refractory to conservative management.

As reported by Kalani et al, complex aneurysms are the single largest indication for direct EC-IC bypass (Kalani et al. 2015). The complexity of an aneurysm may be due to its shape, broad neck or its absence, calcified or atherosclerotic neck, extensive aneurysm thrombosis, or incorporated origin of important vessels (Tamargo 2008). In any such case, treating the aneurysm by clipping or coiling would require sacrificing a major vessel (Soldozy et al. 2019). Other indications include inaccessible sites, such as intracavernous aneurysms (Tamargo 2008).

Surgery of certain skull base tumor encasing the internal carotid artery (ICA), or the vertebral artery (VA) poses a challenging task which sometimes demands sacrificing a major artery and, subsequently, a bypass procedure of the resected segment. The most common

tumors in this group are meningiomas, although the procedure is used in treatment of other entities. Due to the advances in radiosurgery, the procedure has witnessed a dramatic decline in popularity, since tumor remnants encasing arteries are amenable to this non-operative modality (Natarajan et al. 2007, Sekhar et al. 1999).

Cerebral arteries appearing as a “puff of smoke” on cerebral angiography are landmark feature of the moyamoya disease (Scott and Smith 2009). The finding is due to collateral vessels surrounding the constricted brain arteries. If the constriction is primary the condition is called the moyamoya disease; if, on the other hand, the constriction is secondary, it is called the moyamoya syndrome (Scott and Smith 2009). It is a progressive occlusive disease which has a wide presentation – from asymptomatic to transient or persistent neurologic events, or intracerebral, subarachnoid, and intraventricular hemorrhage (Kim 2016). Medical treatment is used to manage complications and active treatment lies with various surgical procedures that have been developed with the aim to revascularize the ischemic parenchyma. Revascularization procedures are either direct or indirect and include: i) STA-MCA anastomosis; ii) encephaloduroarteriosynangiosis (EDAS); iii) encephaloduroarteriomyosynangiosis (EDAMS); iv) pial synangiosis; v) omental transplantation (Kim et al. 2016). Despite lack of robust evidence from randomized controlled trials moyamoya is considered the largest indication for EC-IC bypass procedures (Kalani et al. 2015).

Results of the EC-IC bypass and the COSS study failed to show benefits from the EC-IC procedure for revascularization of occlusive cerebrovascular disease. However, the results of the trials are to be interpreted with caution, due to design issues, in particular that of the EC-IC bypass (Kalani et al. 2015). The procedure is nevertheless offered to patients with proven reduced blood flow and who remain symptomatic despite medical treatment, since it was shown that the bypass procedure helps to restore cerebral hemodynamics (Leblanc 1987, Kawamura et al. 1994).

PREOPERATIVE EVALUATION

Before even considering surgery, all patients should undergo a thorough general medical examination to rule out comorbidities that are known to be associated with a less than optimal outcome. Patients who are not candidates for surgery are directed to alternative treatments or no treatment at all, if such decision confers a lower risk. To definitively establish whether or not a patient has an indication to undergo a cerebrovascular bypass procedure, imaging studies are a *sine qua non* and include brain computerized tomography (CT) and CT-angiography, or, alternatively, magnetic resonance imaging (MRI) and MR angiography and digital subtraction angiography (DSA), which are followed by blood flow assessment studies. In general, the decision to perform a revascularization is done based on preoperative data; however, in some cases the decision is made intraoperatively. When assessing blood vessel morphology in aneurysm cases, particular aspects which are evaluated include the features of the aneurysm itself (presence of calcification or thrombi, size and shape), status of the vessels surrounding and arising from the aneurysm, and status of the donor, graft, and recipient vessels. Vessel grafts, both the SVG and the RAIG, are assessed by ultrasonographic imaging. Additionally, the Allen test is performed when the RA is harvested as a graft, to assess arterial blood flow to the hand, i.e., to screen for patients at risk of

ischemic damage to the hand in case the RA is sacrificed. Intraoperatively, blood flow and graft patency are assessed using indocyanine green (ICG) angiography and Doppler sonography. Preoperatively, patients undergoing a revascularization procedure are administered acetylsalicylic acid to improve graft patency. As with other types of surgical procedures, prophylactic intravenous antibiotics are also administered. If a RA or SV grafts are harvested, intravenous heparin is administered. Anesthesia is tailored to enable intraoperative neurophysiologic monitoring (somatosensory, motor, and brainstem evoked potentials) for intraoperative ischemia and minimize possible secondary injury during temporary arterial occlusion; the latter measures include inducing burst suppression and elevating blood pressure in non-ruptured aneurysm cases and maintaining normotension in ruptured cases.

TECHNIQUES

Brain revascularization procedures are divided into two categories, according to the aim of the procedure: i) flow augmentation bypasses (to treat cerebral ischemia); and ii) flow replacement bypasses (to replace a sacrificed vessel in complex aneurysm and tumor cases). This can be achieved using different approaches and techniques, donor and recipient vessels and interposition grafts. With regard to the donor artery, bypasses are divided into the EC-IC and IC-IC category. Intracranial-to-intracranial techniques include “local” procedures (in situ, reimplantation, reanastomosis, and interpositional bypass) and circle of Willis reconstructions (e.g., interpositioning grafts to restore flow between the MCA and ACA/PCA). The most common EC-IC procedures are the STA-MCA bypass and the ECA-MCA bypass and their respective variations. The spectrum of the reported revascularization procedures and technical nuances is wide (Table 3) and it is beyond the scope of this chapter to describe all of them; instead, the technical aspects of the STA-MCA bypass, the most common revascularization procedure, are summarized and serve as a representative example of the EC-IC bypass in general.

In most cases, the recipient artery is the insular (M2) or the opercular (M3) segment of the MCA, although other segments can be used. At the beginning of the procedure, before the craniotomy, the donor vessel (usually the STA) is dissected for a minimum length of 5 cm and mobilized. If grafting is planned, a segment of the SV or RA is harvested, bearing in mind to mark the proximal end of the venous graft. Next, a craniotomy (usually a pterional craniotomy) is performed, allowing an exposure of the Sylvian fissure and the recipient vessel. After dural incision, the M3 branches are identified and traced back inside the Sylvian fissure. The aneurysm is exposed and the arterial segment proximal to the aneurysm is exposed for proximal control. The distal end of the STA is clamped proximally, transected elliptically and flushed with 1% diluted heparin to prevent thrombosis. The donor vessel stump is fish-mouthed to fit the recipient vessel opening. The recipient vessel is trapped and the recipient site is prepared between two temporary clips by means of a longitudinal arteriotomy approximately 2.5 times as long as the diameter of the vessel, and then irrigated with the heparin solution. Under temporary occlusion, an end-to-side anastomosis is performed using interrupted and continuous 10-0 nylon sutures. First the heel of the mouth of the donor artery is sutured to the recipient arteriotomy site; then the apex of the mouth is

sutured, followed by a continuous suturing of first the posterior and then the anterior wall of the recipient vessel. After suturing the anastomosis, the temporary clips are removed and the aneurysm is either clipped or trapped. The patency of the anastomosis and successfulness of aneurysm exclusion is assessed intraoperatively using ICG angiography and Doppler ultrasonography.

Finally, the dura is sutured, bearing in mind not to damage or occlude the donor vessel. Caution is also exercised when fixing the craniotomy and a burr hole is enlarged to prevent compression on the donor vessel. A suction drain is placed onto the exposed cranium and soft tissues carefully approximated.

POSTOPERATIVE EVALUATION

Standard postoperative evaluation includes a DSA or, alternatively, CTA/MRA on the first postoperative day and routine bedside assessment – donor artery palpation to check pulsations and ultrasonographic evaluation. All patients are administered aspirin and blood pressure is regulated during the first week not to exceed 140 mmHg. Patients are discharged at 7-10 postoperatively and clinical and radiologic follow-up is scheduled at latest three months postoperatively.

COMPLICATIONS

Peri- and postoperative complications can be grouped into two categories: i) general neurosurgical complications; and ii) bypass-related specific complications. The former include postoperative hemorrhage and cerebral ischemia, brain edema, elevated intracranial pressure, seizures, cerebrospinal fluid leaks, septic and aseptic meningitis, wound infections and dehiscence, among others. The latter include bypass occlusion (with or without graft) due to thrombosis or vasospasm. To lower the risk of graft thrombosis in revascularization cases, antiaggregation and anticoagulation regimes have been tailored and usually include clopidogrel, aspirin, and heparin. At our institution, the first case was reported of a successful off-label eptifibatide use in a patient who underwent an urgent STA-MCA bypass procedure for treatment of an MCA (M2) aneurysm (Stambolija et al. 2017).

REVIEW OF PUBLISHED SERIES

For the purpose of this chapter, we performed a systematic review of the literature with the aim of identifying published series of aneurysm cases treated by revascularization techniques. We performed a Medline search (via PubMed) using the search terms “aneurysm,” “bypass,” and “revascularization” No other limitations were imposed. References of the included studies were hand-searched for additional relevant items. Series published in publication types other than peer-reviewed journal articles were not included. Overall, 52 studies were included (Table 1).

Most of the studies were published in the last decade (27, 51.9%) and the majority were from the United States (27, 51.9%) and Japan (9, 17.3%), three from China (5.8%), two from the Netherlands, Taiwan, India, Italy and South Korea (3.8% each), and one study (1.9%) from Canada, Switzerland, and United Kingdom (Table 1). There were 1397 cases of aneurysms treated by revascularization procedures, among the 2634 identified cases; other were either cases in which revascularization procedures used for indications other than aneurysms (e.g., skull base tumors or vascular diseases), or aneurysm cases treated by techniques other than revascularization (different endovascular or open surgical techniques). Overall, the largest series were from the USA ($n=430$), India ($n=177$), and two from the same author from Canada ($n=171$; $n=160$). Two of the studies report exclusively pediatric cases; in the remaining studies patients were most commonly in sixth decade of life and women were predominant in all but three studies. The majority of series were reports of giant aneurysm cases (15 studies), followed by, complex aneurysms (9 studies), blood blister-like aneurysm cases (7 studies), and very large aneurysms (3 studies); others were reports of mixed cases (i.e., aneurysms and tumors or vascular diseases) (Table 1). Aneurysm locations included the cervical CA, petrous CA, cavernous CA, bifurcation of the CA, PCoA, OphA, ACoA, ACA (different segments), MCA (different segments), PCA (different segments), PCA, PICA, BA, and VA (Table 1). The proportion of patients presenting with SAH ranged from 0% to 100%; in general, studies reporting lower incidence of SAH were those on very large and giant aneurysms of the anterior circulation, while studies that reported the highest incidence were small cohorts of patients with ICA BBL aneurysms. Other presentations included headache, cranial nerve deficits, seizures, hydrocephalus, mass effect, cerebrovascular accidents, transitory ischemic attacks, thromboembolism, carotid-cavernous fistula symptoms, hemiparesis, intracerebral hematoma, and finally, a significant proportion of patients was asymptomatic (Table 2). Most commonly reported types of revascularization procedures were EC-IC bypass (40 studies, 76.9%), followed by reports of both EC-IC and IC-IC bypass procedures (9 studies, 17.3%), and only two studies (3.8%) reported of exclusively IC-IC bypass procedures (Table 1). Among the most common techniques was the high flow EC-IC bypass, using either the saphenous vein or the radial artery as the interposition graft. However, numerous other techniques were used for different indications: this is delineated in Table 3. Graft patency rates ranged from 66-100% and aneurysm obliteration rates were over 90% in most reports (Table 1). Morbidity ranged from 0-60% and was highest in the BBL ICA cohorts, which also we the most likely aneurysms to rupture; however, there were also reports on BBL ICA aneurysms which reported 0% morbidity (Table 1). Mortality ranged from 0-44.5% and was highest in a report from 1986, on giant aneurysms of the anterior circulation (Table 1). In general, BBL ICA aneurysms cases had high mortality, which is not surprising, given their complexity and thus high rate of rupture and morbidity.

ILLUSTRATIVE CASES

Case 1

A 67-year-old Caucasian woman presented with an acute onset right-sided limb weakness, altered state of consciousness, and frontal headache to an Emergency Department at an external hospital. At index examination she was drowsy, confused, obeyed motor commands and had neck stiffness. An urgent brain CT was performed which showed an intracerebral hematoma and SAH in the left frontotemporal region. CT angiography showed an aneurysm of the left MCA. The patient had a Hunt and Hess grade III and the hemorrhage was graded as being Fisher grade 4. Telemedicine consultation was referred to our Department and the decision was made to immediately transport and operate on the patient.

Upon admission, a follow-up CT/CT angiography was performed which showed a giant irregular-shaped dissecting aneurysm on the parietal branch of the cranial M2 trunk of the left MCA (Figure 1). The patient underwent surgery under total intravenous anesthesia (TIVA); eptifibatide 1 mcg/kg/min was administered intraoperatively and 72 hours postoperatively. After inserting an external ventricular drain through the right Kocher point, a left frontotemporal craniectomy was performed, the dura incised and the Sylvian fissure dissected. A large aneurysm was identified on the MCA bifurcation; M1, temporal (tM2) and frontal M2 (fM2) were incorporated into the aneurysm, while the aneurysm itself was thrombosed and surrounded by a hematoma. First the neck of the aneurysm was clipped and then temporary clips were placed on the M1, tM2 and fM2 and then the aneurysm was resected. To reconstruct the vascular architecture, an end-to-end M1 to tM2 and STA to fM2 bypasses were performed (Figure 2). Intraoperative ICG angiography showed patency of the revascularized segments. The dura and bone were reconstructed in a fashion to accommodate the traversing STA. Postoperative angiography showed patency of the M1 to tM2 bypass and

no flow in the STA to fM2 bypass (Figure 3). The patient was weaned from the ventilator on the third postoperative day; upon emerging from sedation he was found to have a mild right-sided limb weakness and difficulties with spatio-temporal orientation. Both deficits gradually improved and she was discharged three weeks postoperatively. The patient recovered well and was readmitted six months postoperatively for a cranioplasty procedure with a discrete aphasia and an otherwise normal neurological status.

Figure 1. CT angiography showing a giant aneurysm on the parietal branch of the left MCA (A); reconstructed image (B).

Figure 2. Intraoperative image (A) showing the end M1 to tM2 (arrow) and STA to fM2 bypass (asterisk); schematic drawing (B).

Figure 3. Digital subtraction angiography showing patency of the M1 to tM2 bypass (A) and no flow in the STA to fM2 bypass (B).

Case 2

A 28-year-old Caucasian man presented with a grand-mal epileptic seizure to an Emergency Department at an external hospital. At initial examination he complained of a headache and had no neurological deficits. Urgent nonenhanced brain CT showed SAH in the left Sylvian fissure and an M1 aneurysm, which was confirmed on the DSA (Figure 4). The patient had a Hunt and Hess grade I and was transferred to our Clinic for an angiography and treatment. The angiography showed a giant aneurysm on the bifurcation of the left MCA and the patient was scheduled for surgery on the following day. During the night the patient became unresponsive, bradycardic and hypotensive and an urgent CT showed progression of the SAH.

An urgent surgery was performed during which a ruptured MCA bifurcation aneurysm was identified as the source of bleeding. The neck of the aneurysm was clipped as, well as an M2 branch arising from the dome of the aneurysm (Figure 5). To revascularize the parenchyma supplied by the sacrificed vessel, an STA-M2 bypass was performed; intraoperative ICG angiography showed bypass flow patency. Postoperative angiography showed occlusion of the bifurcation of the left MCA and a patent STA-MCA bypass (Figure 6). Postoperative stay in the ICU was complicated by a respiratory insufficiency which prolonged ventilator weaning. Eventually, the patient was extubated 13 days postoperatively and transferred to a hospital at his place of residence with a right-sided limb weakness and sensory dysphasia.

Figure 4. CT showing SAH in the left Sylvian fissure and an aneurysm of the left MCA (A); the finding is confirmed by digital subtraction angiography, on the anterior-posterior view (B) and lateral-lateral view (C).

Figure 5. Intraoperative image (A) showing the clipped and resected aneurysm (arrow) and the M2 branch arising from the dome of the aneurysm (asterisk); schematic drawing (B).

Figure 6. Postoperative angiography (A – anterior-posterior, and B – lateral-lateral view) showing occlusion of the bifurcation of the left MCA and a patent STA-MCA bypass.

CONCLUSION

Despite lack of robust evidence from quality clinical trials, cerebral revascularization techniques are indispensable in modern neurosurgical settings. The review of cohorts presented in this chapter supports this view and shows a progressive growth in numbers of reported cases worldwide, which is likely associated with a growth in the number of performed procedures. It is our firm belief that these techniques will not go extinct in the years to follow. On the contrary, they remain the only hope for a significant subset of patients suffering from cerebrovascular diseases. What is needed to further strengthen their use are high-quality data from well-designed studies.

ABSTRACT

Vascular pathophysiology in central nervous system (CNS) tumors and its management during surgical procedures are complex issues, sparking to this date a heated debate. Brain tumors can, in fact, distort the already variable vascular anatomy, posing a significant challenge during tumor removal. Furthermore, although venous sacrifice can cause devastating consequences, under specific circumstances, it can be desirable to help creating/widening a surgical corridor in order to increase the extent of tumor resection. It is therefore mandatory to develop intraoperative tools which allow to outline, both before and during tumor resection, the patient's unique CNS circulation and the relationships between the tumor and the surrounding brain vessels. Finally, in the possible event of an unexpected artery or vein damage, the neurosurgeon would surely benefit from a tool able to predict the consequences of this injury in real-time in order to reverse the situation, when possible.

Indocyanine green video-angiography (ICG-VA) is an intraoperative technique designed to highlight superficial vessels during neurosurgical procedures; the FLOW 800

analysis software (*Carl Zeiss Meditec*), which is able to provide a semiquantitative evaluation of cerebral blood flow, has further expanded the usefulness of ICG-VA, especially in neuro-oncological surgery.

In this chapter, the authors present their extensive experience with ICG-VA and FLOW 800 analysis software during surgical removal of CNS tumors; in particular, they identified 5 possible applications of ICG-VA and FLOW 800 in this field: a) extradural analysis to explore sinuses patency and bridging veins anatomy before dural opening; b) ICG temporary clipping test to verify the feasibility of venous sacrifice in deeply located tumors; c) pre-resection analysis to identify pathological vascularization (arterialized veins, neo-angiogenesis and distorted regional venous outflow); d) analysis during and after tumor resection to identify the effects of an unintended/compelled venous sacrifice or of an unintentional arterial damage in real-time and to evaluate vessels patency and parenchymal perfusion after tumor removal; e) pre-myelotomy analysis during intramedullary tumors excision to highlight the posterior median sulcus.

In conclusion, ICG-VA with FLOW 800 analysis can be considered a useful method to provide reliable and real-time intraoperative information regarding the patient's unique vascular anatomy during microsurgical removal of CNS tumors. In particular, this technique can help the decision-making process concerning vascular management during neuro-oncological procedures, thus minimizing the risk of surgical complications.
